Provisioning services: Refer to products provided by ecosystems, including food (derived from both plants and animal products), fuel, fresh water, genetic resources, biochemicals and pharmaceuticals etc. Materials such as wood, and minerals for construction, or ornamental products such as animal skins and fibers for clothing or decoration are also considered provisioning services.

Regulating services: Relate to benefits resulting from the regulation of ecosystem processes such as water purification, waste management, air purification, pest control, erosion and storm protection, climate regulation, water regulation and pollination (Fig. 1).

Cultural services: Refer to the intangible benefits offered by ecosystems, which relate to people’s use of ecosystems for recreational activities, intellectual and spiritual development, social cohesion, cultural heritage, and aesthetic value.

Fig. 1 Categories of ecosystem services. (Developed from MEA, 2003; TEEB, 2010.)

Supporting services: Are otherwise referred to as “Habitat Services” (TEEB, 2010), and encompass the services which ecosystems offer in terms of creating the conditions necessary to provide a basis for all other ecosystem services and maintain the conditions for life on Earth (MEA, 2003). This includes provision of natural habitats, water and nutrient cycling, soil formation, and oxygen generation through photosynthesis. The key difference between supporting services and provisioning or regulating services, is that while humans do not directly benefit from supporting ecosystem services such as soil formation, they do in contrast benefit directly from the food provided from the soil.

Ecosystem Services Approach to Natural Resource Management and Development

In recent years, the Ecosystem Services approach has been widely adopted within natural resource management (Daily et al., 2009; Plant and Ryan, 2013; Moore et al., 2017), as a useful framework which captures not just the monetary value of the natural environment, but also the intrinsic value locked within our rivers, seas, and landscapes. Here the concept of Total Economic Value (TEV) proves a useful tool, as it highlights the value that society derives from all natural capital (TEEB, 2010; Koundouri, 2015), thereby aiding decision-making in relation to resource allocation and management.

Furthermore, ecosystem services provide a critical link between the natural environment and human wellbeing (Akinsete et al., 2019) and offer a means to articulate the contribution of nature to human life, economic activity and societal development. Concepts such as the “cascade model” (Haines-Young and Potschin, 2010) seek to illustrate these relationships, charting the connections between ecosystems, the services they provide, and the benefits these afford society. In recent years, the discourse has expanded to incorporate the link between the benefits to society in the context of human well-being, as well as socio-political processes such as policy development, decision-making, and planning and implementation of management strategies. Such models provide vital frameworks, through which ecosystem services, and the value of nature to society, and be further embedded into crucial decision-making processes.

Initiatives such as the Natural Capital Project (a partnership between Stanford University, the Chinese Academy of Sciences, the University of Minnesota, the Stockholm Resilience Centre, The Nature Conservancy, and the World Wildlife Fund), aim to integrate the value nature provides to society (ecosystem services) into all major decision-making processes in order to improve human and natural wellbeing. World Resources Institute, has taken this mandate a step further, actively targeting decision-makers in order to raise awareness within this sector (World Resources Institute, 2008) (Fig. 2). Despite ecosystem services being increasingly identified as a key tool to nurture societal development with consideration for the natural environment, there is still a fundamental gap in the recognition of the concept in terms of its role in supporting sustainable development, and implementation of global agendas such as the Sustainable Development Goals (SDGs) (United Nations, 2016). While tools such as MESH (Mapping Ecosystem Services to Human well-being), developed by the Natural Capital Project, are working towards supporting ecosystem services-based decision-making in the context of the SDGs and the SDG indicators (Natural Capital Project, 2016), there are still calls for ecosystem services to undertake a more prominent role in the implementation of the SDGs and the drive towards sustainable development (Wood et al., 2017).

The Ecosystem Services of Freshwater Bodies

Freshwater is a cross-cutting element which in fact integrates several ecosystem services, providing multiple benefits to various aspects of human life. The type and number of ecosystem services provided are unique to each individual ecosystem, and different types of freshwater bodies offer a host of different ecosystem services depending on the type of water body as well as its location, and condition. The core ecosystem services provided by different types of water bodies, are presented below.

Fig. 2 Interactions between the natural environment and society. (Developed from: Haines-Young and Potschin, 2010.)

Surface Water Bodies: Rivers & Streams, Lakes, Ponds and Wetlands

Majority of the global population relies on rivers, streams and lakes for fresh water supply, providing access to water for drinking, domestic use, sanitation, agricultural and industrial use. Not only do these water bodies provide water for alternative uses such as hydropower production, and transportation, but they also provide food, materials and pharmaceuticals in the form of products derived aquatic organisms which live in these ecosystem habitats. This group of water bodies also play a key role in maintaining water quantity via nutrient filtration, and over the long term, in nutrient cycling and soil formation (Feld, 2013). In addition, rivers, streams and lakes along with floodplains and wetlands, are critical for the control of floods and erosion. Wetlands and floodplains, are a nexus point of the terrestrial and aquatic ecosystems, which play a unique and vital part in the provision of ecosystem services and are generally considered to be the most valuable ecosystems (UNEP-Secretariat of the Convention on Biological Diversity, 2015). As well as providing both agricultural and aquacultural produce for food, biofuel, fiber and raw materials, wetlands also carry out integral processes such as water purification, flood and erosion control, and nutrient cycling. Additionally, the riparian zones of wetland ecosystems serve as nature-based carbon capture facilities and thereby mitigate climate change. Arguably one of the most vital ecosystem services offered by wetlands is the support of vast amounts of biodiversity, providing habitat for a number of rare and endangered species as well as most of the world's migratory bird populations. This assortment of biodiversity in turn make wetlands particularly attractive locations for tourism and recreational activities such as hiking, fishing, bird watching, photography and hunting (Ramsar Convention on Wetlands, 2005; Millennium Ecosystem Assessment, 2005a,b).

Groundwater

With aquifers providing drinking water for up to 2 billion people, and irrigation for approximately 40% of the world's food, groundwater is essential for the storage and retention of clean water for domestic, industrial and agricultural uses (NRC, 1997; Morris et al., 2003; Bergkamp and Cross, 2006). Groundwater bodies and their systems are necessary for maintaining the hydrological cycle through discharge and recharge, thereby maintaining other freshwater bodies such as rivers and streams, while also mitigating against drought by straining freshwater flow during prolonged and extreme dry seasons. In cases where groundwater produces hot springs, they provide cultural ecosystem services such as therapeutic or recreational spas, and serve as heritage sites where such springs are considered sacred or of great aesthetic value (Griebler and Avramov, 2014).

Ice-Caps

While polar ice holds 68% of global fresh water, the least is known about the specific ecosystem services. It is known that polar ice, plays a key role in regulating global temperatures, by reflecting a greater amount of solar radiation and heat (180 W m^{-2} annually), than the annual solar input of 80 W m^{-2} (Nakamura and Oort, 1988). In addition, the polar ice provides a habitat for microbial organisms such as algae and bacteria, and serves as shelter and feeding ground for juvenile krill, along with larger animals like

Table 1 Various Ecosystem Services Provided by Different Freshwater Bodies. (Developed from Aylward et al., 2005; Bergkamp and Cross, 2006; Ramsar Convention on Wetlands, 2005; Millennium Ecosystem Assessment, 2005a,b; Palmer and Richardson, 2008; Feld, 2013; Schallenberg et al., 2013; Griebler and Avramov, 2014; CGIAR Research Program on Water, Land and Ecosystems, 2015; Mitsch et al., 2015; UNEP-Secretariat of the Convention on Biological Diversity, 2015; WWF Global Arctic Programme, 2015; Bock et al., 2018; Malinauskaite et al., 2019.)

		<i>Ecosystem services</i>			
		<i>Provisioning</i>	<i>Regulating</i>	<i>Cultural</i>	<i>Supporting</i>
Freshwater body	Rivers and Streams	• Water (quantity and quality) for consumptive use (for drinking, domestic use, and agriculture and industrial use) • Water for non-consumptive use (for generating power transport/navigation) • Aquatic organisms for food and medicines	• Maintenance of water quality (natural filtration and water treatment) • Buffering of flood flows, erosion control through water/land interactions and flood control infrastructure	• Recreation (river—rafting, kayaking, hiking, and fishing as a sport) • Tourism (river viewing) • Existence values (personal satisfaction from free-flowing rivers) • Cultural values (religious, historical or archeological value)	• Role in nutrient cycling (role in maintenance of floodplain fertility) • Soil formation • Predator/prey relationships and ecosystem resilience
	Wetlands	• Food (agriculture, aquaculture, fisheries) • Peat production for fuel and horticulture Furbearer and other animal harvesting Timber production	• Flood control groundwater replenishment • Shoreline stabilization and storm protection • Sediment and nutrient retention and export • Water purification • Climate change mitigation and adaptation (CO₂ capture)	• Cultural values (religious, historical or archeological value) • Recreation • Tourism (hiking, fishing, bird watching, photography and hunting) • Existence values • Landscape aesthetics • Sites for human relaxation • Ecology education	• Reservoirs of biodiversity • Habitat for rare and endangered species • Wetland functions such as hydric soil development, primary productivity, serving as chemical sources, sinks, and transformers, and water storage
	Groundwater	• Water (quantity and quality) for consumptive use (for drinking, domestic use, and agriculture and industrial use) • Water for non-consumptive us (geothermal and power production, hot springs for medical therapy) • Aquatic organisms	• Erosion and flood control • Climate change mitigation and adaptation (buffer against spatial variability in drought)	• Recreation (hot springs, mineral spas) • Historical/cultural value (sacred springs) • Spiritual knowledge and wisdom	• Maintenance of hydrological cycle (aquifer recharge and discharge)
	Ice-Caps	• Freshwater storage	• Climate change mitigation and adaptation (<i>albedo</i>—heat and solar reflection away from earth)	• Education and knowledge (record of the Earth's climate history preserved in ice cores)	• Habitat for microbial community (algae, bacteria, and small consumers) • Feeding ground for juvenile krill, penguins and seals

penguins and seals. Finally, polar ice is an invaluable source of knowledge and natural history, preserving a record of the Earth's climate in ice cores (Millennium Ecosystem Assessment, 2005a,b; WWF Global Arctic Programme, 2015) (Table 1).

Current Threats to Freshwater and Ecosystem Services

Although critical to natural and human communities, fresh water is threatened by a myriad of issues including overdevelopment, pollution, over abstraction and global warming. The threats to freshwater ecosystems strongly vary in space and time depending on both social and ecological contexts, with immediate impacts on ecosystem services. Needless to say, current concerns over freshwater, among others, focus on the fact that provisioning freshwater services are far from met on a global scale. Today, 748 million people worldwide remain without basic access to drinking water, 2.4 billion people lack access to basic sanitation services, 1 billion people practice open defecation and 1.7 billion people are currently living in river basins where water use exceeds recharge (UN Water, 2015; WWP, 2017).

Provided the increasing population, which is expected to reach 8 billion in 2025, water withdrawals are expected to increase; the business as usual scenario predicts increase in water withdrawals of 22% by 2025 while the crisis scenario foresees 37% increase.

Consequently, the stress to freshwater resources and the need to sustain ecosystem services, also as a means to achieve the targets set towards achieving the SDGs, are becoming increasingly pressing in the coming years (Aylward et al., 2005).

Freshwater bodies are experiencing declines in biodiversity at a far wider extent than the terrestrial ecosystems (Collen et al., 2014), affecting the vitality and survival of species, particularly of the most sensitive ones, like amphibians. The threats to freshwater biodiversity can be summed up to derive from: overexploitation, water pollution, flow modification that may degrade habitats, and human-induced invasion by non-native species. Protection of freshwater biodiversity, is therefore, prioritized but is still comprises a challenge as it is multi-dimensional. The trade-offs between conservation of freshwater biodiversity and human use of ecosystem goods and services, may impose additional threats for the ecosystems and may affect ecosystem functioning and resilience, human livelihoods and biodiversity.

Disturbances or even negative impacts to freshwater ecosystems derive even from recreational activities. The use of lakes and rivers have cumulative impacts on the ecology of the ecosystems and often contribute to high biodiversity losses that are notably higher at freshwater ecosystems in comparison to terrestrial and marine ecosystems. Rivers, in particular, seem to suffer the most by habitat alteration due to recreational activities, such as boating, swimming etc.; 56% of river water bodies were found to significantly suffer from habitat loss and habitat alterations in the E.U. (Fehér et al., 2012; EEA, 2015), with immediate impact on the social value of the ecosystem.

Wetlands, especially mangroves, are among the most threatened freshwater ecosystems. The shallow-water natural floodplains are facing degradation due to urbanization, land use changes, water abstraction and pollution. Wetland loss is associated with losses in biodiversity and decline of critically important ecosystem services of socio-economic significance that include, among others, the stormwater management element, prevention of coastal erosion, nutrient cycling, water purification and reduction of waste load, habitat provision (Sannigrahi et al., 2019). Climate extremes affect wetland vitality and result in increased risk of flooding in the built wetland shores. The ecosystem service beneficiaries, i.e., farmers, consumers, locals, domestic water supply to cover demand, tourists and visitors, face higher levels of uncertainty in relation to the access and availability of the resource (Gómez-Baggethun et al., 2019).

The groundwater aquifers comprise the most widely used water deposits, therefore, suffer severe depletion dropping groundwater aquifers at levels that are considered non-usable. Over-abstraction of groundwater is affecting surface freshwater flows in rivers and lakes, is causing lowering of the water table and land subsidence, increases the cost of abstraction. In coastal areas it is resulting in upwelling and mixing of brines with fresh groundwater, resulting in salinization of groundwater aquifers, the most common type on groundwater pollution (West and Obling, 2014). Although the balance between freshwater and saltwater tends to remain relatively stable, over-abstraction has resulted in massive contamination of groundwater and the linked surface water resources with salt. An estimated 12.9 km³ cubic kilometers of saline groundwater exists in comparison to about 10.5 km³ of fresh groundwater (Gleick, 1996), with direct impacts for water supply and socio-economic services of the resource.

Despite the low attention to sea-ice biomes degradation in relation to the terrestrial and marine biomes, as previously observed (Malinauskaite et al., 2019), today there is increasing concern over the threats to ice caps. The ecosystem services related to climate regulation and biodiversity provided by ice caps are becoming of vital importance for the planet. The threats to ice caps derive from the actual loss of ice extent and reduction of thickness due the average increase in temperature. Even small changes in the ice properties may have long-lasting effects on sea ice, freshwater ice and the dependent ecosystems. The rapidly developing climate change accelerates the impact on ice caps. The climate regulation and hydrological support of ice caps is, therefore, significantly reducing. The interactions of the underline aquatic ecosystems with atmospheric air and solar radiation are also reducing with immediate impacts in primary productivity and biodiversity.

Recommendations on Sustaining Ecosystem Services

Management of freshwater resources should address the multifunctional nature of water, should cover the water and ecosystem needs without jeopardizing the integrity of ecosystem services and the benefits deriving from them for human societies, economies and the environment. Holistic approaches are aiming at human well-being, at ensuring good ecological status and increase benefits to the society. Integration of knowledge, ideas and services are tools to achieve protection of freshwater ecosystems and to engage into holistic management approaches that can be proven beneficial in protecting and sustaining ecosystem services. A holistic management framework of this kind, needs to draw attention to the links between environmental (natural), recreational, socio-economic aspects of freshwater systems while it actively engages into participatory processes that are beneficial for the end users and protective for the local natural environment. On top, ecological restoration of freshwater bodies and of their services can provide multiple social and economic benefits (Rey Benayas et al., 2009).

The Ecosystem-based Approach is an approach that links the direct and indirect contributions of ecosystems to human well-being and emphasizes on the protection and value of ecosystem attributes (Millennium Ecosystem Assessment, 2005a,b). In extent, ecosystem-based water management is in support and sustenance of ecosystem services, thus, sustainable management in aquatic ecosystems that depend on policy integration, engagement and exchange of knowledge, targeting at the protection of natural ecosystems. This approach considers ecological integrity, biodiversity, resilience to change, it is carried out at the appropriate spatial scales, it develops and uses multi-disciplinary knowledge, it builds on social-ecological interactions, it involves stakeholder participation and transparency, it supports policy coordination and incorporates adaptive management concepts, thus, the ability to respond to a range of possible futures, weighting at the same time short-term actions against long-term benefits or alternative actions (Langhans

et al., 2019). Holistic ecosystem-based management allows for trade-offs between the Ecosystem Services while taking societal goals into account. Ecosystem services are engaged, within this framework, to map the impacts of ecosystem changes to human well-being, ultimately aiming at identifying mitigation options or actions for the sustainable use of ecosystems, able to adverse the effects of drivers and pressures and improve quality of life via meeting the sustainable development goals (Apostolaki et al., 2019). This framework works well provided it is initially well defined, it is based on extensive and consistent monitoring and on elaborate evaluation processes. Consistency on governance combined with innovative solutions are key to stakeholder engagement. The benefits deriving are related to open dissemination of processes, while conflicts of transboundary nature or of any other kind are resolved. The ecosystem-based approach comprises the basic tool towards ecological restoration, and action in response to environmental degradation caused by human activities. Restoration is seen as a tool towards regaining ecosystem services, re-establishing contact with nature and improving the well-being for humans and the natural environment.

Abstract

Ephemeral wetlands are habitats with seasonal water body and ephemeral plant cover. Subtypes are shorelines of permanent rivers with fluctuating water level, seasonal pools in climates with variations in rainfall and the ephemeral flush habitat on inselbergs. EW offer extreme environments, shifting from flooding to water shortage. Short-lived annuals, dwarfish perennials and resurrections plants find a niche there. A permanent seed bank (and egg bank for crustaceans) buffers the year-to-year variability. Strong selective forces result in evolutionary processes like convergence, niche constancy, endemism and vicariance of taxa. By sheltering rare and endemic species, EW are jewels of biodiversity.

What Are Ephemeral Wetlands (=EW)? Basic Characteristics and Questions

EW are habitats submerged only part of the year. Plant cover is appearing above-ground for a short period (ephemeral) and characterized by short living annuals and dwarfish perennials.

The following questions will be discussed: (1) How does the combination of abiotic factors change around the world? Can we distinguish different types of EW? (2) What are common ecological traits and which life forms are successful? (3) How do water depth, duration of inundation and time of emergence trigger small-scale vegetation patterns and the seasonal dynamic of pools? (4) What is the role of the seed bank for buffering the year-to-year variability? (5) Are EW colonized by cosmopolites or has each floristic kingdom evolved its own taxa? (6) Finally the impact of humans and conservation issues will be discussed.

Habitat Types According to Abiotic Factors

Fluctuations of the water level are the result of variations in precipitation, evaporation from the water surface, transpiration by plants, surface and groundwater inflow and outflow, infiltration rate, drainage intensity and seepage outflow. According to the combination of landform, hydrology, soil and climate, EW can be classified in three types (Fig. 1: shoreline habitat (=SHH), seasonal pool habitat (=SPH), and the ephemeral flush habitat (=EFH) (Deil, 2005). There is a clear geographical pattern (Fig. 2):

The *shoreline habitat* (=SHH) dominates in perhumid extratropical climates and in mountainous regions of the tropics. It occurs along the shores of permanent freshwaters (shallow lakes, ponds, rivers) with strong seasonal fluctuations of the water level (Photo 1). This water dynamic result from lower precipitation and reduced overland inflow in the dry season and from higher evapotranspiration in summer. With decreasing water level, the shoreline passes through a sequence of ecophases: hydrophase (limnic, deep water), littoral (shallow water), limosal (amphibious, semi-terrestrial) to terrestrial (Hejný, 1971; Hejný and Husák, 1978).

Fig. 2 Global distribution of ephemeral wetland habitats. From Deil, U. (2005). A review on habitats, plant traits and vegetation of ephemeral wetlands—A global perspective. *Phytocoenologia* 35, 533–705.

A special case of SHH are seasonal floodplains. The largest EW of this type is the Pantanal of Mato Grosso in South America. It covers about 200,000 square km during the maximum of the flood pulse (Heckman, 1998). A human-made case of SHH are fish ponds. Exposed pond bottoms offer a niche for ephemeral mud vegetation during summer drainage (Šumberová et al., 2006; Šumberová and Hrivňák, 2013).

The *seasonal pool habitats* (=SPH) are concentrated in the sub-humid areas on both sides of the Tropic of cancer. In climates with seasonal rainfall, rain fed ponds are seasonal too. In Mediterranean regions with winter rain maximum, shallow depressions over stagnant sediment and pools over impermeable rocks are ponded in winter (Photo 2). The pools desiccate completely in early summer. The widely used term “vernal pools” (=VP) refers to spring as amphibic phase and as the main season for plant growth and flowering. In the dry tropics the cycle is inverse with submersion in summer and an amphibic phase in autumn (aestival ponds).

Photo 2 Vernal pool in the aquatic phase with *Ranunculus peltatus* on the basalt plateau Giara di Gesturi, Sardinia, Italy.

VP landscapes occur in California (Holland, 1998), along the Atlantic coasts of Morocco (El Mahidi et al., 2017) and the Iberian Peninsula (Pinto-Cruz et al., 2009; Benavent-González et al., 2014), in Mediterranean Chile (Alvarez and Deil, 2015; Deil et al., 2011), South Africa and SW Australia. The size of the VP ranges from a few square meters in rock pools to several hectares in Moroccan depressions. One of the largest wetlands in the world are the millions of seasonal potholes in the prairie of North America (Van der Valk, 2005).

The catchment areas of SPH are local or the ponds are purely rain fed. The water budget of prairie potholes is dominated by precipitation (85% of water input) and evapotranspiration (78% of output) (Williams, 2006). Overland and subsurface inflow (16%) and seepage outflow (22%) are of minor importance.

Bauder (2005) studied pool hydrology over 20 years near San Diego: Water depth and hydroperiod are strongly correlated with the variability of rainfall. At site in the Great Valley, strong rainfall and high water levels result in outlet swales and seasonal streams,

Photo 3 Nave do Barão, Algarve, Portugal, Karstic depression flooded in April 2018.

overland and in the aquifer (Rains et al., 2006). VP hydrology is better described as mini-catchment than as a pure rainwater-evapotranspiration system. A special case of SPH is flooding by a raising karst water table after strong rainfall, as it occurs in depressions (dolines, poljes) of calcareous landscapes (Photo 3).

The *ephemeral flush habitat* (=EFH): In the perhumid tropics, EW are restricted to runoff-habitats. Ephemeral vegetation colonizes rock pools or occurs on the slopes of inselbergs, furthered by water seeping from mats with perennial plants (Photo 4). Richards (1957) coined the term ephemeral flush vegetation in Western Africa for a short-living plant cover, irrigated by water seeping from the adjacent *Afrotrilepis* mats. This term is now used to describe Inselberg vegetation (Porembski and Barthlott, 2000a). Inselbergs and EFH are common in West and East Africa, India, the Guyana shield (Fig. 2. Rare outliers occur in extratropical regions (SE United States, Southern Portugal, SW Australia).

Biological Characters and Plant Strategies

EW offer an extreme environment. Favorable conditions for growth and reproduction exist only within a short season and year-to-year variability is high. It is a life between inundation and desiccation, every year shifting from flooding to water shortage. The plants are dwarfish (a few centimeters high), above-ground biomass is ephemeral and the vegetation cover is open. Three plant strategy types predominate in EW:

1. *Dwarfish annuals with the ephemeroid syndrome*: They germinate from a permanent seed bank. Some species like *Limosella aquatica* germinate in shallow water and reproduce in the limose phase (amphiphytes); others like *Carex bohemica* germinate on mud in the littoral phase and complete their life cycle under terrestrial conditions (von Lampe, 1996). Characters of the ephemeroid syndrome (= co-evolved adaptive traits) are an extremely high phenological plasticity, a short life span, small growth form (nanism), rapid nutrient turnover, fructification a few weeks after germination and high reproductive effort. Representatives of the tiny annuals come from Cyperaceae, Lentibulariaceae and Scrophulariaceae (all floristic kingdoms), Juncaceae (Holarctic kingdom), Eriocaulaceae (Australia, East Asia), Centrolepidaceae (Australia), Callitrichaceae, Elatinaceae (most floristic kingdoms) (Photo 5) and other families. The ephemeral flush vegetation on Inselbergs is characterized by short living carnivorous succulents from the Lentibulariaceae and Droseraceae (Porembski and Barthlott, 2000a).
2. *Geophytic perennial herbs*: These species survive the dry phase with below-ground perennial organs (thick roots, tubers, bulbs, rhizomes). They resprout and develop leaves under submerged condition. In nutrient poor SHH and SPH dominate slow-growing, long-living stress-tolerators with the Isoetid syndrome (a rosette of long-lived terete leaves with lacunar air spaces, relatively high root biomass) like the fern *Isoetes*. Convergence in isoetid growth is stated by Keeley and Zedler (1998) for genera growing in Californian VP (*Orcuttia*, *Lilaea*, *Navarretia*, and *Eryngium*). In nutrient rich SHH and SPH in tropical climates, higher growing and productive hydro-geophytes such as *Nymphaea*, *Heteranthera*, and *Sagittaria* resprout from subterranean parts and develop floating leaves in the aquatic phase. Flowering and fruit setting happens in the limose phase.
3. *Poikilohydric vascular plants*: A special strategy to cope with water shortage is to desiccate passively, to lose more than 90% of the water content and to remain still alive in a dormant stage until water is again available. Water uptake and return in an active life (e.g., photosynthesis) occurs rapidly in these resurrection plants. Ninety percent of the worldwide species with this water budget strategy occur on Inselbergs in the tropics (Porembski and Barthlott, 2000b; Biedinger et al., 2000). Seasonal rock pools are the preferred habitat of desiccation-tolerant plants with representatives from Xyridaceae, Velloziaceae, Bromeliaceae, Cyperaceae in Southern Africa, resurrection plants are numerous in the genera *Craterostigma*, *Lindernia* (Scrophulariaceae), *Myriothamnus* (Myriothamnaceae), *Xerophyta* (Velloziaceae) a.o. On rock outcrops in Australia, the resurrection strategy is represented by *Borya*.

An extreme example of a resurrection plant is *Chamaejasme intrepidus*, the “fearless giant dwarf.” It colonizes rock pools in the Namib Desert, supports up to 20 desiccation-wetting-cycles per rainy period and can flower 2 days after resurrection (Heilmeyer et al., 2005). A “*Chamaejasme*-strategy” of desiccation tolerance and recovering within some minutes after re-flooding is recorded by McLachlan and Cantrell (1980) for Chironomid-larvae in tropical rock pools.

Fauna of EW and Strategy of Animals in SPH

The short favorable period for growth and reproduction of aquatic animals in SPH and EFH excludes long living predators and competitors like fish. EW however are not totally enemy free, because carnivorous aquatic insects such as larvae of Odonatae, amphibians and other active dispersers colonize VP in the wet season (Brendonck et al., 2002).

Photo 5 *Elatine gussonei* and *Crassula vaillantii* in rock pool on limestone plateau Cava Grande, Syracuse, Sicily, Italy.

The SPH faunal specialists are branchiopods and copepods (Crustacean) and Turbellaria, both passive dispersers (Jocque et al., 2010; Boix et al., 2016). They survive the dry period as eggs and cysts in a dormancy stage (diapause) (Williams, 1998). Branchiopod eggs can survive 20 years without ponding (Holland, 2009). The branchiopods produce enormous numbers of individuals during a short aquatic phase and are the most characteristic faunal element in VP (Guidicelli and Thiéry, 1998). Hundreds of Branchiopoda species live in SPH all over the world, many of them are endemic. One famous representative is the living fossil tadpole shrimp (*Triops cancriformis*). Observations in a pool network over decades are necessary to discover the complete species composition (Fahd et al., 2009).

To buffer the unpredictability of the time and length of the hydroperiod, only part of the egg bank is stimulated to hatching by submersion (diversified bet-hedging) (Simovich and Hathaway, 1997; Ripley et al., 2004). Some species need only a few days from hatching to reproduction. Like in the germination of vascular plants from the seed bank, delayed (by dormancy) and asynchronous hatching avoids depletion of the egg bank by rainfall shortly after desiccation of the pool. Offspring is spread over several years.

Bagella et al. (2010, 2011) studied crustaceans, amphibians, macroinvertebrates and vascular plants in VP on Sardinia over three seasons (filling, aquatic, drying). Each group of organisms has its own seasonal dynamic and beta-diversity pattern. There is low cross-taxon congruence: Vascular plants have high species-turnover rates between the ponds. The duration of the hydroperiod has a stronger impact on the crustaceans. Their beta-diversity is low: dispersal of the cysts and eggs by wind guarantees a meta-population in a pond landscape (Vanschoenwinkel et al., 2008).

Biomass Production, Photosynthetic Pathways and Heterophylly

SPH and EFH are exceptionally unproductive ecosystems, CO₂-limited in the aquatic phase and water-limited in the terrestrial phase (Keeley, 1999). Flat depressions are not filled up over the years by biomass accumulation. Biomass produced in the wet season is re-mineralized in the dry season (Collinson et al., 1995). Pure rainwater systems without lateral inflow of inorganic sediments can persist over thousands of years (Amami et al., 2013).

The variety of photosynthetic pathways used by aquatic and amphibic plants was studied by Keeley (1999) and Pedersen et al. (2011). CAM is recorded for a number of *Isoetes* and *Crassula*-species in Californian VP. It is not an adaptation to the scarcity of water, but to CO₂-shortage. The VP are poorly buffered and have an extreme diurnal fluctuation of carbon availability (Keeley, 1999). *Isoetes* has air chambers in the leaves, where endogenous CO₂ is accumulated at night. CAM enhances underwater photosynthesis and diminishes photorespiration (Pedersen et al., 2011). Semi-terrestrial *Isoetes* can switch from CAM to C₃ photosynthesis in the terrestrial stage.

Heterophylly and development of aerenchyma: Annuals as well as semi-terrestrial geophytes can change their morphology and histology under submergence and anoxic conditions. Shoot elongation, aerenchyma formation and heterophylly as response to flooding are typical for the amphibious fluctuation responders sensu Casanova and Brock (2000). An example is *Eryngium corniculatum* (Photos 6–8).

Photo 6 *Eryngium corniculatum*, aquatic form, Nave do Barão, Portugal.

Photo 7 *Eryngium corniculatum* amphibic form, Nave do Barão, Portugal.

Photo 8 *Eryngium corniculatum*, terrestrial form, Nave do Barão, Portugal.

Small Scale Zonation of Plant Communities

Abiotic ecological factors, which change over short spatial distance, are named ecological gradients. When they act as strong environmental filters for establishment and productivity of plants, the effect is a strong species turnover along this gradient and a small scale arrangement (= zonation) of different plant communities. Vegetation zonation according to water depth, length of inundation and time of emergence is a characteristic feature of temporary ponds (SPH) and emergent shorelines (SHH). Other differentiating gradients can be soil depth and duration of seepage water flow. These gradients determine repetitive patterns of plant communities. Three zonation examples with different climatical, hydrological and geomorphological situations are presented:

West Africa: The spatial sequence of plant communities according to water depth (hydrosere) in seasonal lakes in the Sahelian zone is illustrated in [Fig. 3](#) (from [Müller and Deil, 2005](#)) and [Photo 9](#). It starts in deep water with the free floating pleustophytic Lemno-Pistietum, characterized by duckweed (*Lemna* spp.), water ferns (*Salvinia*, *Azolla*, *Wolffia*), and water hyacinth (*Eichhornia natans*). In water of medium depth (150 to 20 cm) follow the Nymphaeion micranthae-communities. They are dominated by hydro-geophytes (rooting tubers, floating leaves) like water lilies (*Nymphaea* spp., *Nymphoides indica*) and bladderwort (*Utricularia* spp.). The shallow water and the amphibic zone are colonized by communities of the Rhamphicarpo fistulosae-Hygrophiletea senegalensis, a vegetation class of West-African distribution ([Müller and Deil, 2005](#)). The associations of the *Sagittario guayanensis*-Nymphaeion maculatae grow closer to the lake center (maximal 60 cm water depth), the grazing- and trampling-resistant swards of the *Brachiario muticae*-Cynodontion dactyli colonize the nutrient rich amphibic muddy lake margins with short-term

Fig. 3 Spatial sequence of plant communities according to water depth (Hydroseries) of a seasonal pond in the Sahel of West Africa. Modified from Müller, J. V. and Deil, U. (2005). The ephemeral vegetation of seasonal and semi-permanent ponds in tropical West Africa. *Phytocoenologia* **35**, 327-388.

Photo 9 Summer aspect of a Sahelian seasonal lake with ephemeral vegetation (*Nymphaea* div. spec., *Nymphoides indica*, *Ipomoea aquatica*), Mare d'Oursi, North Burkina Faso Photo: J.V. Müller

inundation. *Sagittario-Nymphaeion* is a very colorful vegetation type (**Photo 10**), dominated by hydro-geophytes (*Heteranthera*, *Sagittaria*, *Nymphaea*) and hemicryptophytic Cyperaceae (*Cyperus*, *Fuirena*, *Pycnus*), tolerating strong water level fluctuations.

Zonation in SPH in Mediterranean climates: Vegetation zonation in Californian VP in relation to inundation was studied in detail by Zedler (1987) and Bauder (2000). The sequence of the species according to weighted average inundation classes and inundation-frequency profiles are illustrated in Deil (2005; Fig. 17). The inundation in the pool Centre eliminates true terrestrial species. Only a small number of species is adapted to extended ponding. The desiccation in the terrestrial phase excludes obligate wetland taxa from the outer margin. The amphibic habitat in between offers a unique habitat quality, the evolutionary result is the VP-specific flora (Keeley and Zedler, 1998). Zonation in Moroccan VP was studied by Rhazi et al. (2001a), an example from Portugal is illustrated in Fig. 4.

Photo 10 *Sagittaria-guayanensis*-community with *Nymphaea maculata*, *Nymphoides indica*, *Sagittaria guayanensis*, *Schoenoplectus subulatus*, and *Ipomoea aquatica*, Mare de Kissi, Burkina Faso. Photo: J.V. Müller.

Fig. 4 Model of the seasonal and spatial distribution of vernal pool plant communities in Southern Portugal. From Espírito-Santo, D. and Arsénio, P. (2005). Influence of land use on the composition of plant communities from seasonal pond ecosystems in the Guadiana Valley National Park (Portugal). *Phytocoenologia* **35**, 267–281.

Zonation with EFH: The vegetation mosaic on inselbergs includes seasonal water-filled rock pools, water storing monocotyledonous mats and ephemeral flush vegetation. This spatial pattern was studied in French Guiana by Sarthou (2001). The water storing mats on the slopes are dominated by perennial grasses (*Axonopus ramosus*) and Bromeliaceae (*Pitcairnia geykesii*). On the water film soaking out of the mats develops an open and dwarfish turf, characterized by short-lived bladderworts (*Utricularia* spp.) and poikilohydric ferns (*Selaginella producta*).

Seasonal Dynamics, Year-to-Year Variability and the Role of Seed Bank

The dynamics of climate and flooding regime in SHH and SWH result in a high species turnover in the growing season and allow separating ecophases. The Mediterranean climate with the sequence of wet springs with fluctuating temperatures, and hot, dry

summers initiates a clear separation of cold and warm germinating/sprouting species. This is illustrated by an example from Southern Portugal: due to seasonal dynamic of VP vegetation and very different plant assemblages in March and May, [Espírito-Santo and Arsénio \(2005\)](#) distinguish a spring and a summer zonation. In March, the hydroseries is Peplido-Agrostietum (aquatic), Junco-Isoetum histricis (late emergent) and Loto-Chaetopogonetum (early emergent). In May, the long submerged Junco-Isoetum velati is surrounded by the Eryngio-Preslietum (amphibic) and the Pulicario-Agrostietum (terrestrial) ([Fig. 4](#)).

Year-to-year-variability is a prominent attribute of SHH and SPH. This is a consequence of between-year-fluctuations in precipitation, length of the flooding period and time of emergence of the shoreline. Plant response to drought is individualistic and depends largely on the timing of meteorological events in relation to life-stages ([Bauder, 2005](#)). Such a germination and sprouting ecology can explain the year-to-year-vegetation dynamic and spatial shift of vegetation zones. Inter-annual variability of the floristic composition and species abundance of Californian VP has been studied by [Bauder \(2000\)](#). The observation period included a normal, a wet and a dry year. "Pool species" were more static on the ponding gradient than "edge" species. "Non-pool" species moved in the dry year towards the pool centre and responded to the wet year by shifting towards the dry end of the moisture gradient ([Bauder, 2000](#)).

Permanent plot studies in Morocco by [Rhazi et al. \(2001b, 2009\)](#) confirm inter-annual variability in species diversity, composition and abundance and the spatial shift of the vegetation zones around vernal pools. *Myriophyllum alterniflorum*, abundant in the pool centre in wet years, is totally absent in dry years. *Pilularia minuta* was observed only in some years. Its sporocarps can persist over decades and wait for a good year ([Muller et al., 2009](#)). Enormous changes in population densities were observed for annuals (*Elatine brochonii*).

Time of emergence of shorelines and surface temperatures in the beginning of the amphibic phase can stimulate cold or hot germinating species ([von Lampe, 1996](#); [Pietsch, 1999](#); [Sumberová et al., 2006](#)) and results in different plant communities on exposed pond bottoms from year to year.

Seed bank and germination ecology: The seed bank makes the EW resilient to the inter-annual variability of ponding. A synopsis about seed bank, germination and dormancy, including data from EW, is presented by [Baskin and Baskin \(1998\)](#). VP species in Mediterranean areas were analyzed by [Carta \(2016\)](#), rock pool species in NW Australia by [Cross et al. \(2014\)](#). Inundation experiments and seed bank analysis ([Casanova and Brock, 2000](#) for SE Australia, [Bliss and Zedler, 1998](#) for California) show, that from an identical soil sample, different plant communities can be awakened by varying flooding regimes. Most species occur in the seed bank over a broader range of the inundation gradient and microrelief than in the above-ground vegetation ([Metzner et al., 2017](#); [Aponte et al., 2010](#)). In a certain year, only parts of the seeds are stimulated to germinate. The results are strong year-to-year changes in species composition and a spatial shift of the vegetation belts. The annuals shift around, the geophytes and the hemicryptophytes form a spatially constant matrix. The perennials react to the fluctuating water conditions with a changing sprouting rate and a different period and duration of above-ground appraisal ([Rhazi et al., 2001b, 2009](#)).

Major trends in seed bank characteristics and reproductive strategy are:

1. A persistent seed bank: Seeds are viable for decades or even more than one hundred years ([Poschod and Rosbakh, 2018](#)). Like seeds, the cyst stage of vernal pool shrimps can survive for decades ([Belk, 1998](#)). This is an adaptation to short-term availability and temporal unpredictability of the habitat. Ponding stimulates only part of the seed bank to germinate ([Brock, 2011](#)).
2. A high plasticity in germination: Secondary dormancy is enforced by unfavorable conditions like darkness or low oxygen level (imposed by water) ([Bliss and Zedler, 1998](#)). Physiological dormancy is the most common type of dormancy in amphibious plants ([Baskin and Baskin, 1998](#)). Soil perturbation and light are mobilizing seeds from deeper soil layers.
3. A high vegetative plasticity of adults, variability in plant size and in fruitset. Average and maximal seed output per plant vary enormously (*Anagallis minima* 250 to 6380 seeds; *Lythrum hyssopifolia* 2550 to 74,500) ([Salisbury, 1970](#)).

Evolutionary Processes and Large Scale Biogeographic Patterns

EW is a habitat occurring on all continents (except Antarctic) and in all biogeographic regions. When comparing the floristic composition of EW at the global scale ([Deil, 2005](#)), we can state three evolutionary processes: (1) convergent evolution of similar life forms and strategy types in different families, replacing each other in the same niche in several floristic kingdoms (niche equivalence). (2) A great number of phylogenetic lineages (mostly genera) entered the EW environment early in their evolution, spread globally, remained linked to this habitat (niche constancy) and evolved geographical vicarious species in different parts of the world. (3) A remarkable stock of taxa (most species), specialized to EW (stenoeious taxa), are restricted to a small area (stenochorous = endemic taxa). The latter species are an important contribution to global biodiversity. The evolution processes and the resulting biogeographical patterns will be presented now in more detail.

Convergence and Niche Equivalent Taxa

The niche of dwarf ephemeroid annuals is occupied by Juncaceae in the Holarctic kingdom, by Orcuttieae in California, Centrolepidaceae in Australia, Restionaceae in the Capensis, Eriocaulaceae in Australia and East Asia, and by Cyperaceae, Crassulaceae, Calitrichaceae, Ranunculaceae, Gentianaceae, Elatinaceae, and Apiaceae in all floristic kingdoms.

Photo 11 Poikilohydric plants in rock pools of the Yemeni Escarpment (SW Arabian Peninsula): *Craterostigma pumilum* and *Selaginella yemenensis*.

The niche for poikilohydric vascular plants with the xyroid syndrome occupy Xyridaceae (pantropical), Cyperaceae (*Afrotrilepis* in the Old World, *Trilepis* in the New World), Velloziaceae (*Xerophyta* in the palaeotropical, *Vellozia* in the neotropical region), Scrophulariaceae (*Craterostigma*, *Lindernia*, *Chamaegigas* in the palaeotropical region) (**Photo 11**), and *Borya* (Australian region). The xyroid families are not only niche-equivalent, but also have the same ecosystem function: These mat-forming taxa store the precipitation water and accumulate soil. The continuous supply of seepage water out of the mats on slopes of Inselbergs allows the development of the ephemeral flush vegetation below them (Porembski and Barthlott, 2000a).

Niche Constancy in EW Lineages and the Evolution of Geographical Vicarious Species

The database with floristic samples all over the world (Deil, 2005) shows clearly, that some phylogenetic lineages adapted quite early in geological time to seasonally wet conditions and later on evolved and speciated within this environment without radiating into other habitats (niche constancy). Some high ranked taxa (families, tribes, genera) are linked exclusively to EW and evolved geographically vicarious species. Examples are the families Isoetaceae, Marsileaceae, Centrolepidaceae, and genera like *Isoetes*, *Marsilea*, *Pilularia*, *Navarretia*, *Downingia*. A clear preference to the amphibic and limose environment is also expressed in generic names like *Amphibromus*, *Hygrophila*, *Limnophila*.

Moor (1937) was the first to underline that phylogenetically old taxa of trachaeophytes (*Isoetes*, *Marsilea*, *Pilularia*) are associated with EW. An explanation might be the extremely low productivity in SPH and EFH. At other sites, the dwarfish life form is outcompeted by advanced and more productive taxa. Branchiopoda as living fossils might have found a refugium in VP as habitat with low predation pressure (Zedler, 2003).

Isoetes (=quillwort =Merlin's grass) plays a major role in SPH all over the world. The genus is documented by fossils since the early Triassic (Jermy, 1990; Pigg, 2001). It is the oldest clade of CAM plants (Keeley and Rundel, 2003). 200 to 250 *Isoetes* species are known today (Photo 12). A pattern of geographical vicarious species in VP is recorded from the United States by Taylor and Hickey (1992) and from Spain by Molina (2005). When several species co-occur, they occupy different niches in the gradients of soil depth, soil fertility and inundation period. Geographical vicariance and niche partitioning can also be observed in *Marsilea* and *Pilularia* (Marsileaceae). Both genera are adapted to EW (Cook, 1990). They sprout from long-living (up to 100 years!) sporocarps. Juveniles are submerged, adults floating, emergent or terrestrial. Vicariance patterns occur in many other taxa specialized to EW (e.g., *Juncus*, *Limosella*, *Crassula*, *Hydrocotyle*, *Eriocaulon*, *Xyris*) (for details see Deil, 2005). The small size and the spatial isolation of the EW habitat reduce gene flow and favor allopatric speciation.

Regional Endemism and Biodiversity of SPH

Besides common genera and a very few species growing in EW in many continents, a classification of the available data set at the species level according to floristic similarity (the approach of Braun-Blanquet, 1964) results in clearly separated clusters (=classes), restricted to different floristic kingdoms. These classes have their own unique species, which contribute to the endemism of phytochorological areas. This pattern is demonstrated by the example of SPH (Fig. 5):

High ranked floristic-sociological clusters (classes) in the New World are the Downingio bicornutae-Lasthenietea fremontii in California (Barbour et al., 2003, 2005), replaced in Mediterranean South America by the Plagiobotryo pratensis-Navarretietea

Photo 12 *Isoetes hatrix* on rock outcrop with interflow, Serra de Monchique, Portugal.

Fig. 5 Global distribution of phytosociological classes of seasonal pool vegetation. 1. *Downingio bicornutae*-*Lastenietea fremontii*. 2. *Plagiobotryo pratensis*-*Navarretietea involucretae*. 3. *Isoeto-Nanojuncetea/Isoetetalia duriei*. 4. *Rhaphicarpus fistulosae*-*Hygrophiletea senegalensis*. 5. *Centrolepidi aristatae*-*Hydrocotyletea alatae*. ?. undescribed class in South Africa and Namibia.

involucretae. Both classes are connected by a few species (amphi-neotropical elements sensu Raven, 1963) such as *Lasthenia kunthii*, *Psilocarphus brevissimus*, *Downingia pusilla*, *Navarretia involucreta*. Their high disjunct distribution is the result of long-distance dispersal by water birds.

Vernal pools are the state habitat of California (Keeley and Zedler, 1998). Fifty-five percent of the VP plant species are endemic to the Californian phytogeographical sector (Barbour et al., 2005). The *Downingio*-*Lastenietea* range from Oregon to Baja California. They are characterized by (1) *Downingia* spp. (Campanulaceae), a genus highly diversified in co-evolution with oligolectic bee species as pollinators (Thorp, 2007; Holland, 2009), by (2) *Orcuttia* spp., glandulous annual grasses with several genera, (3) by *Lasthenia* (18 species), *Limnanthes* (14 species), and by *Navarretia* spp. (Polemoniaceae) (Spencer and Porter, 1997).

The *Plagiobotryo pratensis*-*Navarretietea involucretae* (Deil and Alvarez, n.d.; Bliss et al., 1998; Deil et al., 2011) occur in Mediterranean Chile from 32 to 43°S (Alvarez and Deil, 2015) (Fig. 5) (Photos 13 and 14). The class is characterized by a number of *Plagiobotrys*, *Eryngium* and *Isoetes* species, by the endemic annuals *Blennosperma chilense*, *Centipeda elatinoides*, *Micropsis nana* a.o.

Photo 13 Vernal pool in a grazed *Acacia-caven* pseudo-savanna near Vilches, Prov. Maule, Chile.

Photo 14 *Plagiobotrys pratensis* (Boraginaceae), name giving species for VP vegetation in Chile; near Chillan, Prov. Biobio, Chile.

Because of their dwarfish and ephemeral character, some of these species have a hidden abundance and are often overlooked. Some were recently discovered for Chile (*Hydrocotyle cryptocarpa*) or rediscovered after some decades (*Lepuropetalum spathulatum*, [Alvarez et al., 2012](#)).

The plant communities of SPH in the Western Palaearctic belong to the class Isoeto-Nanojuncetea/order Isoetetalia, ([Mucina et al., 2016](#)). The Isoetetalia are of circum-mediterranean distribution ([Fig. 5](#)). Characteristic taxa are *Isoetes* spp., *Juncus* spp., *Crasula vaillantii*, *Scirpus cernuus*, *Lythrum* spp., *Marsilea strigosa*, *Pilularia minuta* a.o. ([Photo 15](#)). With the dominance of inconspicuous annual *Juncus* species from section *Tenageia* ([Photo 16](#)), European VP are less spectacular than Californian goldfields with blooming *Lastenia* spp. ([Holland, 2009](#)). By sheltering many rare and endemic species, they are however a botanic jewel of Southern Europe and Northern Africa ([Braun-Blanquet, 1935](#)).

Photo 15 *Illecebrum verticillatum*, *Ranunculus saniculifolius*, and *Isoetes velata* in vernal pool near Ben Slimane, Morocco.

Photo 16 *Juncus capitatus*, Monchique, Serra de Monchique, Portugal.

The SPH North (vernal pools) and South (aestival pools) of the Sahara (Fig. 2) have no species in common. The floristic contrast between Palaearctis and Palaeotropis is in the SPH as accentuated as in the flora in general. In sub-Saharan West Africa, the vegetation of SPH and SHH belongs to the Rhamphicarpo fistulosae-Hygrophiletea senegalensis (Müller and Deil, 2005). Hydrogeophytes from the Nymphaeaceae play a major role in amphibic mud vegetation. Details for zonation, life forms and dominant species are given in Fig. 3. The plant communities in the Mediterranean part of SW Africa (Capensis) are poorly studied but have their particular flora, different from NW and West Africa.

EW in SW Australia belong to the class Centrolepidi-Hydrocotyletea alatae (Pignatti and Pignatti, 1994, 2005). Fifty-six percent of its flora are SW-Australian endemics, characterized by Centrolepidaceae, Asteraceae, Apiaceae (*Hydrocotyle*), Cyperaceae, Juncaginaceae, and Stylidiaceae. Remarkable is the nearly total absence of Juncaceae. The dwarf rush niche is occupied by the Centrolepidaceae. The flora of seasonal flooded clay pans in SW-Australia is also characterized by a high endemism rate, with *Stylidium* (24 species), *Schoenus* (21), *Drosera* (18), *Isolepis* (13), and *Centrolepis* (9) (Gibson et al., 2000, 2005).

Major Anthropogenic Threats

Habitat Modification, Destruction, and Eutrophication

EW are rare and small-sized landscape elements, separated from each other and unpredictable in timing. With these characteristics, they are vulnerable habitats per se. EW are very sensitive to hydrological changes in their catchments (filling-in and drainage to avoid ponding respectively excavation and damming-up to achieve permanent water bodies). The main reason for the decline of SHH is the reduction of water table dynamics in lakes and old river beds by hydrological regulations and the direct destruction of the habitat by tourist resorts at shorelines. The SPH are threatened by drainage and transformation into arable land. In SW-Australia, 90% of VP and 95% of the clay pans were destroyed by agriculture (Pignatti and Pignatti, 1994; Gibson et al., 2000). Holland (2009) estimates the loss of grassland with VP in the Central Valley of California by urbanization and agriculture to 87%. A VP landscape in Morocco has lost 23% of the pools and 61% of pool surface in the period 1955–2001 (Rhazi et al., 2012).

The narrow geographical distribution of VP plants and animals and the small size of the populations make them vulnerable to extinction (Barbour et al., 2005). A survey of large branchiopods in SPH in Morocco showed an enormous decline in number of populations and species from 1987 to 2014 (Van den Broeck et al., 2015). The EFH is not so threatened, because inselbergs are holy places in many societies and in general of low economic interest (except exploitation by quarries).

Many VP taxa such as *Isoetes* spp. are specialized to oligotrophic conditions and need clear water bodies. Input of nutrients and sediments from the surrounding agricultural land is a great risk. Well conserved and species rich SPH in Japan and Morocco are restricted to ponds located in woodland (Rhazi et al., 2001a; Shimoda, 2005).

Expansion of EW Species and Shift Into Human-Made Habitats

An opposite trend to habitat loss and species extinction is the anthropogenous spread of EW taxa. There are two different processes: (1) an extension into similar habitats in other floristic kingdoms, (2) the shift from primary to human-made habitats.

An extension of the ephemeral wetland flora can be observed for example in annual *Crassula*-species. *C. tillaea* from Europe is naturalized in VP in Chile and South Africa. SPH in New Zealand have 13 native and 6 naturalized *Crassula* species (Johnson and Rogers, 2003). The “globalization” of the EW flora will result in the long term in a certain trivialization of the communities and a loss of floristic specificity of the floristic kingdoms. Sometimes are species, evaluated as threatened or vulnerable in their native area, classified as “aggressive neophytes” or “invasive species” in other regions. This concerns for example species of palaeartic origin like *Lythrum hyssopifolia* and *Ranunculus flammula* in New Zealand (Johnson and Rogers, 2003), or *Lythrum hyssopifolia* and *Anagallis minima* in California (Barbour et al., 2005; Gerhardt and Collinge, 2003).

Some EW species shift from primary to human-made habitats such as rice fields or fish ponds. In the tropics, amphibic shorelines and seasonal pools are often transformed into rice fields (Müller and Deil, 2005; Shimoda, 2005). Many annual SHH and SPH species like *Rhamphicarpa fistulosa* and habitat generalists among the fauna remained in this environment and became rice weeds (Lawler, 2001; Nowak et al., 2015; Rodenburg et al., 2014). *Heteranthera limosa* for example, originating from seasonally flooded playas in the Southern USA, became a troublesome weed in rice fields in the United States and in Europe.

In the temperate climate of Central Europe, fish and irrigation ponds can serve as secondary habitats for amphibic plants of SHH. Changes in fish pond management in the 20th century (extended submersion period, the abandonment of summer drainage, liming or herbicide spraying of the exposed pond bottom, eutrophication) have caused a decline of Isoeto-Nanojuncetea species in Carp ponds in Central Europe (Šumberová et al., 2006, 2012).

Climate Change and the Role of Grazing

EW systems are very sensitive to hydrological changes, but by a buffering seed/egg bank quite resilient to variations in precipitation. They shelter a wait-for-the-rain biodiversity. Every year is a good year for something in the pool. Pyke (2005) modeled the effect of climate change for VP in California. A broad spectrum of pools in nature reserves guarantees survival of rare Branchiopods. Shallow pools are more threatened by urbanization than by climate change. Pyke and Marty (2005) showed that cattle grazing can mediate climate change impact on SWH: It reduces transpiration by removing biomass and lowers infiltration rate by trampling. Inundation periods get longer despite higher temperatures. Excluding pasturing reduces the ponding period and favors invasive exotics versus native VP plants (Marty, 2015). These results from grazing experiments in California are confirmed by studies in VP in Morocco (Bouahim et al., 2010). Drainage, plowing and eutrophication of pools are greater threats for VP than grazing. EW support high disturbance frequencies, but suffer from intensive disturbance, which destroys the seed bank.

EW have always be submitted to grazing and trampling by large herbivores, searching for drinking-water (Photo 17). The plants are adapted to pasture pressure by nanism and creeping growth form (avoidance of grazing) or by a regeneration capacity (tolerance strategy) from subterranean parts and clonal growth. Moderate grazing reduces the competition of productive perennials. Trampling on wet surfaces creates open patches and germination niches for short-living ephemerals in permanent grassland. Ground disturbance by cattle grazing and rooting by pigs and wild boar is for example recommended for the maintenance of *Ranunculus revelieri* populations in mainland France and Corsica (Grillas et al., 2004). Pawing and wallowing by bison destroys the perennial plant cover in the Great Plains in North America. This creates ephemeral pools, deepens playa lakes, favors mudflat species and facilitates the establishment of *Marsilea mucronata* (Uno, 1989).

Photo 17 Horses grazing in vernal pool embedded into cork oak landscape, Plateau de Zaer, Ben Slimane, Morocco.

Conservation and Restoration

EW are included by the RAMSAR convention into vulnerable and protected wetland habitats. In the European Union, a certain conservation status is guaranteed by designating SPH as priority habitats.

Although seeds and resting eggs can be dispersed by wind, water and waterfowl, a remarkable regional endemism in plants and Crustacean can be stated. Beta diversity (dissimilarity in species composition from pool to pool) and year-to-year variability are high. Only many pools of different size, depth and hydroperiod and a network of nature reserves over a broad set of climatic variables can conserve the overall biodiversity of the VP flora and fauna (Pyke and Fisher, 2005; Alexander, 2007; Gómez-Rodríguez et al., 2009). An outstanding example is the network of about 3000 VP with different pool depth and hydroperiods, protected in the National Park Doñana in SW Spain (Díaz-Paniagua et al., 2010).

Restoration and mitigation projects of SPH in California have been quite successful. Inoculation by transfer of autochthonous soil and seed bank overcomes dispersal limitations and speeds up the trend towards natural pool characteristics after some years (Collinge et al., 2013). Aquatic invertebrates need more time to reestablish. Guidelines for VP restoration are presented by Schlatter et al. (2016).

EW as Model Ecosystems for Ecological Research

By their extreme low productivity (carbon limited in the aquatic phase, water limited in the terrestrial phase) EW are unique ecosystems. They offer a niche for dwarfish annual plants and for slow growing perennials with ephemeral above-ground biomass. Animals find a nearly enemy free habitat. SPH and EFH are islands in space and time. They are small and easy to manipulate for ecological experiments and can serve as model ecosystems in ecology, evolution, population and conservation biology. Various theories, concepts and models can be tested such as island biogeography, niche theory, connectivity, competition, dispersal limitation, founder effects, genetic drift, meta-population, speciation etc. (De Meester et al., 2005; Emery et al., 2008; Brendonck et al., 2010).

Abstract

Wetlands are globally diverse ecosystems that occur between terrestrial and aquatic environments. The degree of flooding is the main control on wetland vegetation, which varies from shallow water wetlands with submerged and floating-leaved plants, to emergent marsh and treed swamp. Wetlands support unique flora and fauna, from duckweed to mangrove trees and from frogs to hippopotamus. Humans exploit them for water, rice and fish, but wetlands also provide key services, such as flood attenuation, coastline protection, water purification and carbon regulation. Despite these benefits, humans have drained or converted over half of global wetlands. Extensive wetlands remain, but many are threatened by altered flooding regimes, invasive species, nutrient enrichment, contamination and climate change. Conservation efforts must focus on protecting wetlands and especially on maintaining key ecological processes on which wetlands rely.

What are Wetlands?

Wetlands, as their name suggests, occupy transitional zones between terrestrial environments and permanently-flooded or aquatic environments. They are dominated by wetland vascular plants, or macrophytes, and they occur where periodic or permanent flooding produces soils with low oxygen conditions, which forces the biota, particularly rooted plants, to adapt to flooding (Keddy, 2010). Wetlands have existed since vascular plants first evolved and colonized land, 430 million years ago in the early Silurian period (Greb et al., 2006).

We know wetlands by many names: bog, fen, peatland, moor, mire, muskeg, marsh, slough, prairie pothole, wet savannah, dambo, rice paddy, wet meadow, salt marsh, swamp, carr, pocosin, mangrove swamp, mangal, bottomland, and riparian zones, to give just a few names for wetlands in the English language. This list bears witness to the rich and regional language we use for wetlands. But this list also attests to the underlying diversity of wetland ecosystems.

Several regional systems categorize wetlands into different types, based on their landforms, flooding regimes, nutrient regimes, peat formation or their vegetation, but no global system exists to describe wetlands (Keddy, 2010; Mitsch and Gosselink, 2015). Two complementary approaches are commonly used to describe wetlands. The first considers their large-scale landscape setting, and the second considers their vegetation.

Wetlands occur in different broad landscape settings: slope wetlands, depression wetlands, extensive mineral flats, extensive organic flats or peatlands, riverine or floodplain wetlands, lacustrine fringe wetlands and tidal fringe or coastal wetlands; (Fig. 1; Brinson, 1993). Each wetland type occupies a distinct geomorphology setting, and each also has distinct water sources and patterns of water movement through the wetlands.

When wetland vegetation is considered, five broad wetland types are generally recognized: shallow water wetlands, marshes, swamps, bogs and fens.

1. Shallow water wetlands are the most aquatic wetland type. They occupy shallow riparian zones of rivers and littoral zones of lakes and ponds and are dominated by floating-leaved and submersed aquatic plants (Fig. 2A).
2. Marshes are mostly flooded but are occasionally exposed. They are dominated by rooted herbaceous plants with stems and leaves that emerge above the water level. They generally accumulate little peat (Fig. 2B). Freshwater marsh has distinct vegetation from salt marsh, a type of coastal wetland.
3. Swamps are at least periodically flooded but with less flooding than other wetland types. They are dominated by woody plants, either trees or shrubs. They also accumulate little peat (Fig. 2C). Mangrove swamps are a particular type of coastal wetland along protected subtropical or tropical coasts (Fig. 2D).

Fig. 1 General wetland landforms, following the hydrogeomorphic classification of wetlands (Brinson, 1993). The inverted triangle and dashed line indicates the water table in adjacent uplands.

4. Bogs are peat-accumulating wetlands, or peatlands, which are primarily rain-fed and are consequently nutrient-poor and acidic (pH 3–5.5). Bogs have a range of flooding environments and are dominated by peat mosses (*Sphagnum*), sedges, dwarf shrubs and scattered evergreen trees. Because they are rain-fed, bogs are also referred to as ombrotrophic peatlands (Fig. 2E).
5. Fens are another type of peatland that also receives groundwater inputs, and as such are less nutrient-poor and less acidic (pH > 5.5) than bogs. Again, a range of flooding conditions occur. They are dominated by other mosses, sedges, grasses, and scattered shrubs and trees. They are also referred to as minerotrophic peatlands (Fig. 2F).

Other wetland types could be added, such as wet meadows between marsh and swamps. Many wetlands also do not easily fit into these classes, as for instance tropical peat swamps, which are treed swamps that accumulate thick peat deposits.

Wetlands and Flooding

Flooding is the key factor that controls wetland ecosystems. It dictates the type of vegetation and key ecological processes such as decomposition and nutrient cycling. The extent of flooding is a function of the hydrology of the wetland, and more specifically the water balance. The water balance is a simplified way to view how water enters and exits wetlands (Fig. 3). For inland wetlands, inputs include precipitation, surface inflow and groundwater discharge, and outputs are from evapotranspiration, surface outflow

Fig. 3 Elements of a water balance in wetlands. Changes in water storage (ΔV) is a function of inputs of precipitation (P), surface runoff into the wetland (S_i) and groundwater discharge into the wetland (G_i), and outputs of evapotranspiration (ET), surface runoff out of the wetland (S_o) and groundwater recharge from the wetland (G_o). Where there is tidal influence, there are also tidal exchanges (T).

and groundwater recharge (Mitsch and Gosselink, 2015). Coastal wetlands also have tidal exchanges. When water inputs exceed outputs, flooding increases.

Oxygen diffuses 10,000 times slower in still water than in the air, and once a soil is flooded, oxygen diffuses even slower through the voids between the particles of wetland soils (Reddy and DeLaune, 2008). In consequence, once a wetland is flooded, the floodwaters and the surfaces of wetland soils are well-aerated, but oxygen below the soil surface is rapidly consumed by microbes and other biota (Fig. 4). Once flooded, wetland soils soon begin to suffer from low oxygen levels, a condition called hypoxia. With longer flooding duration, the oxygen becomes depleted, a state known as anoxia. Soil compounds of nitrogen, iron, manganese and sulfur also become chemically modified as flooding duration increases and oxygen is depleted (Ponnamperuma, 1972; Reddy and DeLaune, 2008). Methane gas is even produced from organic matter under anoxic conditions. Several of these modified compounds are toxic to plants (Kozłowski, 1984). As a result, plant roots and other wetland biota must not only survive through the low oxygen conditions found in flooded wetland soils, they must also contend with some toxic compounds produced by flooding.

Different wetlands have different duration of flooding, frequency of flooding and depth of the water table or the water level relative to the ground surface. The seasonal pattern of inundation above and below the soil surface is known as the hydroperiod (Reddy and DeLaune, 2008; Mitsch and Gosselink, 2015). However, sometimes the hydroperiod is defined more strictly as simply the duration of standing water in a wetland (Wellborn et al., 1996; Semlitsch, 2000; Batzer, 2013). The hydroperiod, along with the quality of soil organic matter and the availability of nutrients, determines the amount of oxygen that is available in wetland soils (Reddy and DeLaune, 2008). Plant roots, as discussed below, also strongly influence the amount of oxygen in wetland soils.

It is useful to contrast the seasonal hydroperiods of a few different wetland classes and consider the extent and timing of soil aeration with which wetland vegetation must contend.

Extensive organic wetlands, or large peatlands, such as bog and fen, have narrow water level fluctuations (Ingram, 1983; Fig. 5A). This produces extended anoxic conditions, which limit decomposition and the internal cycling of nutrients, and favor the accumulation of peat. Different flooding microhabitats occur in peatlands, from flooded pools >1 m deep to rarely flooded hummocks elevated 20–50 cm above the mean water table (Rydin and Jeglum, 2013), but all have relatively narrow water level fluctuations.

Lacustrine fringe wetlands, such as those along the Great Lakes of North America, are subject to wide seasonal water level fluctuations, with superimposed wind-driven short-term fluctuations, called seiches (Fig. 5B). Wetland vegetation types toward the upper end of this flooding gradient, such as swamp, wet meadow and, to a lesser extent, marsh, only have periodic flooding and consequently have respite from extended anoxic soil conditions. The water level fluctuations also allow more exchanges of nutrients and biota with the adjacent lake (Morrice et al., 2004).

Tidal fringe wetlands, or coastal wetlands, such as salt marshes or mangrove swamps, are subject to tides, with alternating flooded and exposed conditions once or twice each day (Fig. 5C; Friess et al., 2012; Van Loon et al., 2016). This flooding regime is superimposed upon longer-term water level fluctuations associated with lunar cycles, between neap tides and spring tides, and with those associated with occasional storm surges. Soils of tidal wetlands consequently alternate between hypoxic and more aerated

Fig. 4 Changes in relative concentration of soil compounds following flooding After: Reddy, K. R. and DeLaune, R. D. (2008). Biogeochemistry of wetlands: Science and applications, Boca Raton: CRC Press.

Fig. 5 Examples of annual hydroperiod curves in (A) a boreal minerotrophic peatland in Sweden in 2006 (Peichl et al., 2014); (B) a lacustrine wetlands along Lake Erie, USA/Canada, in 2017 (NOAA, 2018); (C) a microtidal mangrove swamp, in southern Florida, United States, in 2011 (Castañeda and Rivera-Monroy, 2018); and (D) a tropical floodplain along the Amazon River at Tabatinga, Brazil in 2017 (SO HYBAM, 2018). Elevations are relative to the ground surface or a local reference point, as indicated. Measurements were taken at hourly intervals (A–C) or daily intervals (D).

conditions on a frequent basis. The tides also allow for frequent exchanges of nutrients, organic matter and biota between the wetlands and the adjacent estuarine or marine environments.

Riverine wetlands are only inundated when the rivers flood. Extreme examples occur in the floodplain forests of the Amazon basin of South America, where water levels fluctuate over >12 m each year (Fig. 5D; Junk et al., 2011). These floodplain forests consequently shift from flooded anoxic environments to drained aerated environments, for several months at a time. The floods act as pulses that permit extensive exchanges of sediment, organic matter, nutrients and biota between the river channel and its floodplain (Junk et al., 1989).

Flooding and Wetland Vegetation

Flooding has profound but different impacts on different wetland plants (Sculthorpe, 1967; Hutchinson, 1975; Blom, 1999; Banach et al., 2009; Keddy, 2010). Consider an idealized transect along a water depth gradient bordering a river or lake, beginning from the most flooded to the least flooded wetlands sites (Fig. 6). Vegetation appears in zones depending on the extent of flooding.

Submerged aquatic macrophytes, such as milfoil (*Myriophyllum*) and bladderwort (*Utricularia*), and rooted floating-leaved macrophytes, such as water lilies (Nymphaeaceae), occur in shallow water wetlands, the most aquatic wetland habitats, which are predominantly to permanently flooded. Further upslope, in periodically exposed environments, is a zone of emergent macrophytes, such as cattail (*Typha*) and arrowhead (*Sagittaria*), rooted in wetland soils, but with their leaves extending above the water surface. This is marsh. Finally, shrubs, such as willows (*Salix*) or alders (*Alnus*), and trees, such as larch (*Larix*) or tupelo (*Nyssa*), occur toward the top of the flooding gradient in only periodically flooded environments, in swamp. Free-floating macrophytes, such as duckweeds (Lemnaceae) and water cabbage (*Pistia*), may occur across this flooding gradient. Algae also grow on plants and other surfaces across this gradient and can make up a substantial portion of primary productivity in some wetlands (McCormick et al., 1998; Adame et al., 2017). Bryophytes, such as peat mosses (*Sphagnum*) and brown mosses (Amblystegiaceae), are generally only abundant where water levels fluctuations are low, as in peatlands.

These different types of wetland plants have different adaptations to flooding. Submersed aquatic macrophytes are well adapted to completely aquatic environments. Their leaves lack a waxy cuticle, are thin and often have a large surface to volume ratio to facilitate the diffusion of oxygen and other substances between their tissues and the water column (Sculthorpe, 1967; Hutchinson, 1975). They can even use dissolved inorganic carbon during photosynthesis, instead of carbon dioxide, which makes them even more suitable to aquatic environments (Sculthorpe, 1967; Hutchinson, 1975; Pedersen et al., 2013).

Rooted floating-leaved macrophytes and emergent macrophytes extend their rhizomes and root systems into the flooded wetland soils. They can withstand some hypoxia in their roots and rhizomes, at least temporarily, through metabolic adaptations (Kozłowski, 1984; Blom, 1999). However, their principal strategy is to avoid hypoxia, through morphological adaptations. They have air channels within their stems and roots, called aerenchyma, which allow for air to circulate from leaves and stems above the water level to the rhizomes and roots in flooded wetland soils (Fig. 7; (Sculthorpe, 1967; Hutchinson, 1975; Jung et al., 2008; Sorrell and Hawes, 2010)). The aerenchyma not only provides oxygen to the roots and rhizomes, it also can aerate the flooded soils immediately around the plant roots (Reddy and DeLaune, 2008; Lai et al., 2012). This effect can facilitate the survival of less flood-tolerant species in the wetland soils nearby (Callaway and King, 1996). However, many emergent plants still prefer less flood duration (Campbell et al., 2016), and many will die back when they are continuously flooded for three or more years (Harris and Marshall, 1963; van der Valk, 1994). Seeds of many emergent plants also prefer to germinate under unflooded conditions (van der Valk, 1981), and as a result, periodic exposed conditions are needed to regenerate many species of emergent marsh vegetation.

Most woody plants lack any morphological adaptations to oxygenate their roots (Kozłowski, 2002; Parolin, 2009). They must rely on physiological adaptations to withstand flooding. They die after a year of continuous flooding, although a few woody wetland species can withstand flooding for 2–3 years (Valle Ferreira and Stohlgren, 1999; Kozłowski, 2002). This is why trees and shrubs are limited to swamps, the wetland type with the least flooding duration. Mangroves are exceptions. They are shrubs and small trees, but they can survive longer flooding because they have aerial roots known as pneumatophores, which transport oxygen to buried roots via aerenchyma (Srikanth et al., 2016).

Fig. 6 An idealized transect across a wetland from shallow water wetlands through emergent marsh to swamp. The lower elevations are almost continuously flooded, while the upper elevations of the wetland are only periodically flooded during high water periods.

Fig. 7 Cross-sectional views of aerenchyma in shoots of wetland plants: (A) arrowhead, *Sagittaria sagitifolia* subsp. *Leucopelata* var. *edulis*, (B) water milfoil, *Myriophyllum spicatum* and (C) crowfoot, *Ranunculus cantoniensis*. The arrows indicate aerenchyma. After: Jung, J., Lee, S. C. and Choi, H. K. (2008). Anatomical patterns of aerenchyma in aquatic and wetland plants. *Journal of Plant Biology* **51**, 428–439.

Other Controls on Wetland Vegetation

Fertility is the second principal factor controlling wetland vegetation (Keddy, 2010). Many wetlands, such as salt marshes, freshwater marshes and swamps, are quite productive, with net primary productivity ranging between 1.5 and $>2 \text{ kg m}^{-2} \text{ year}^{-1}$ (Bradbury and Grace, 1983). Their productivity even exceeds that of intensively farmed agricultural land. However, not all wetlands are productive. Peatlands, for instance, have low net primary productivity, between 0.3 and $1 \text{ kg m}^{-2} \text{ year}^{-1}$. The supply of macronutrients, mainly nitrogen and phosphorus, is responsible for these differences in productivity among wetlands.

For instance, diverse infertile herbaceous wetlands exist in temperate regions, each with their own assemblage of wetland species (Fig. 8). Because of the low nutrient supply, these wetlands have low productivity and are dominated by short-statured species. In contrast, fertile herbaceous wetlands with high nutrient supply become dominated by only a few tall productive species, such as cattail (*Typha*) or common reed (*Phragmites*; Moore et al., 1989). When infertile wetlands receive increasing nutrient supply, the few taller competitive dominants replace the diverse short-statured species, in a process mediated by the competition for light. Many species of conservation concern are also short-statured, and are consequently restricted to infertile, unproductive wetlands (Moore et al., 1989).

Differences in vegetation between wetlands can also be a result of differing micronutrient supply. For instance, both macronutrients such as nitrogen and phosphorus are scarce across peatlands, but fens have a larger supply of calcium than bogs (Fig. 9). This is because bogs are only rain-fed, while fens also receive groundwater inputs. Fens, in consequence, have different species assemblages from bogs, have more rapid nutrient cycling and are more productive (Sjörs, 1950; Bridgman et al., 1996; Wheeler and Proctor, 2000; Keller et al., 2006).

Disturbances, defined as processes that substantially reduce the biomass of vegetation, also have profound influences on the vegetation of wetlands (Keddy, 2010). For instance, flooding by beaver damming is a disturbance because it drowns trees and shrubs. Other examples of disturbance include high river flows which erode river floodplains, ice which gouges shorelines in boreal regions, tropical cyclones which produce erosive waves and high salinity pulses in coastal wetlands, and fire in subtropical and tropical wetlands (Salo et al., 1986; Guntenspergen et al., 1995; Kotze, 2013; Lind et al., 2014). Many wetlands, such as emergent marshes, are adapted to these disturbances. They accumulate large banks of seed in the soil. These seeds consequently allow the vegetation to rapidly recover following severe disturbances (van der Valk, 1981; Keddy and Reznicek, 1986).

Grazing by herbivores is a more targeted type of disturbance that affects some wetlands (Bakker et al., 2016; Wood et al., 2017). Extreme examples include the overgrazing of subarctic coastal marshes by snow geese, or subtropical marshes by nutria, or constructed marshes by muskrat (Kerbes et al., 1990; Shaffer et al., 1992; Kadlec et al., 2007). These herbivores can efficiently transform productive emergent marsh to unvegetated mud flats. Wetland vegetation, at least submersed, floating-leaved and emergent macrophytes are more nutrient-rich, with a lower ratio of carbon to nitrogen than terrestrial vegetation, which explains why fauna prefer wetland plants as food (Bakker et al., 2016).

Other factors that control wetland vegetation include competition among plants, the burial of vegetation by sediment in floodplain and deltaic wetlands and salinity in coastal wetlands (Keddy, 2010).

Wetland Fauna

Many animals are dependent upon wetland environments at some point during their life cycle. An eclectic list could include species of mosquitoes, dragonflies, caddisflies, aquatic beetles, crayfish, crabs, snails, fish, frogs, salamanders, turtles, crocodilians, waterfowl, wading birds, rodents and a few large mammals.

One way to consider the animals in wetlands is to examine the wetland food webs (Montague and Wiegert, 1990). Herbivore-based food chains, where animals directly eat vascular plants, are important in some wetlands, as pointed out above for waterfowl and large rodents (Bakker et al., 2016; Wood et al., 2017). But in many wetlands, the food webs are based upon plant detritus and the bacteria and fungi that feed off it, or upon the microalgae attached to wetland surfaces (Fig. 10). Invertebrate animals feed from

Fig. 10 Food web in a coastal salt marsh, with a grazing food chain along the top and a detrital and microalgal food chain on the bottom. After: Montague, C. L. and Wiegert, R. G. (1990). Salt marshes. In: Myers, R. L. and Ewel, J. J. (eds.) *Ecosystems in Florida*. pp 481–516. Orlando: University of Central Florida Press.

subtropical wet prairies, salt marshes, mangrove swamps and even peatlands (Murkin, 1989; Belicka et al., 2012; Jassey et al., 2013; Abrantes et al., 2015).

Fish utilize the more aquatic habitats found in wetlands. Different species use them as spawning grounds, nursery habitat for juveniles, or as feeding grounds for adult fish. Fish play important roles in the food webs of riverine wetlands, lacustrine wetlands, salt marsh and mangrove swamps (Minello et al., 2003; Petry et al., 2003; Junk et al., 2007; Nagelkerken et al., 2008; Lee et al., 2014; Trebitz and Hoffman, 2015). Fish also move from wetlands to more aquatic habitats. They consequently contribute to wider aquatic food webs in adjacent rivers, lakes, estuaries and nearshore marine ecosystems.

Amphibians are quintessentially associated with freshwater wetlands. They include frogs, toads, salamanders, newts, sirens, and amphiomas. Some amphibians use wetland habitats as larva and then inhabit more aquatic or terrestrial habitats as adults. Others, such as larger frogs, inhabit wetlands throughout their life cycle. Amphibian use of wetlands depends primarily on the duration of flooding and the presence of fish predators (Wellborn et al., 1996; Semlitsch, 2000; Baldwin et al., 2006). Small ephemeral depressional wetlands with only seasonal flooding can have high amphibian use and diversity, in part because they are fishless, whereas permanently flooded wetlands have different amphibian species, adapted to counter fish predation.

Several groups of birds depend on wetlands, including waterfowl, such as ducks, geese and swans, and wading birds, such as herons, cranes, flamingos, rails, jacanas, avocets, shorebirds and ibis (Batt et al., 1989; Sierszen et al., 2012; Holopainen et al., 2015). Many inland and coastal wetlands are globally recognized as Important Bird Areas for their role in providing nesting or migratory stopover habitat for wetland birds (<http://www.birdlife.org/>).

A few mammals are also emblematic of wetland habitats. For instance, beavers (*Castor* sp.) act as ecosystem engineers by damming small watercourses and creating wetlands in much of North America and parts of Eurasia (Naiman et al., 1988). Another noteworthy example, capybaras (*Hydrochoerus hydrochaeris*), the world's largest rodent, inhabit the vast floodplain wetlands in South America (Corriale and Herrera, 2014). Or consider hippopotamus (*Hippopotamus amphibius*) in sub-Saharan Africa, which, by means of their large bodies moving through wetlands, actually control the geomorphology of African wetlands (McCarthy et al., 1998). A less evident example would be the Bornean orangutan (*Pongo pygmaeus*), which has its last strongholds in the peat swamps of southeast Asia (Posa et al., 2011).

Where Are Wetlands Found?

Wetlands occur on all continents, except on Antarctica. They cover at least 12.1 million km² (Davidson et al., 2018), or roughly 9% of the global land area, excluding Antarctica (Fig. 11). Approximately 93% of wetland area occurs inland on the continents, while

Fig. 11 World distribution of wetlands and wetland complexes. Data from the Global Lakes and Wetlands Database (Lehner and Döll, 2004).

the remaining 7% occurs along marine coasts or in estuaries (Davidson et al., 2018). A few wetlands are quite large, with the 11 largest wetlands or wetland complexes covering a total of 5.8 million km² (Fraser and Keddy, 2005; Keddy et al., 2009). The top four wetlands are representative and contrasting. They include two major boreal peatlands, the West Siberian Lowland in Russia and the Hudson Bay Lowland in Canada and two extensive tropical swamps in the Amazon River basin in South America and the Congo River basin in central Africa.

Wetland Ecosystem Goods and Services

Wetlands provide significant ecosystem goods and ecosystem services that support human well-being (Table 1; Millenium Ecosystem Assessment, 2005; Liqueite et al., 2013; Reis et al., 2017; IPBES, 2018; Ramsar Convention on Wetlands, 2018). Ecosystem goods include foods such as fish and grains, water, fuels and other biotic products. For instance, riverine, lacustrine and coastal wetlands support critical fisheries of fish and crustaceans, which provide essential protein for nearby settlements (Welcomme et al., 2010; Lee et al., 2014; Abrantes et al., 2015; Trebitz and Hoffman, 2015). Rice (*Oryza sativa* [Asian rice] or *Oryza glaberrima* [African rice]) is also widely cultivated in subtropical and tropical wetlands that have been converted to agricultural use (Gopal, 2013). It is a staple food that feeds billions of people. Another key ecosystem good from wetlands is water. Humans extract water near wetlands for drinking water, irrigation and other uses, although water extraction affects the flooding regimes upon which wetlands depend (McCartney and Acreman, 2009). Some wetlands also provide non-food goods, such as timber, thatching material, fuel wood, honey and waxes (Uddin et al., 2013).

Wetlands not only provide goods for human use, but they also provide key ecosystem services, for which we do not pay, that help to regulate and support broader ecosystems and human societies. For instance, headwater and riverine wetlands store water

Table 1 Principal ecosystem goods and services provided by wetlands

Ecosystem services	Examples in wetlands
<i>Ecosystem goods</i>	
Food provision	Fisheries (fish, mollusks, crayfish, crab, shrimp), waterfowl, rice, wild rice, sago palm, wild vegetables
Water storage and provision	Replenishment of groundwater resources, water for human consumption
Biotic materials and biofuels	Non-food uses, including timber, fibers, resins, medicines, genetic resources, fuel peat
<i>Regulating and supporting ecosystem services</i>	
Water flow regulation	Reduction of flood risks in rivers and consequent reduction in erosion and flood damage
Coastal protection	Wave attenuation and protection against storm surges in coastal wetlands
Water purification	Filtering and degradation of nutrients, organic wastes and pollutants
Climate regulation	Carbon regulation through uptake, storage and sequestration of CO ₂ as peat; release of methane
<i>Cultural services</i>	
Recreation and tourism	Birdwatching, ecotourism
Symbolic and aesthetic values	Spiritual and aesthetic enjoyment

Adapted from: Millenium Ecosystem Assessment (2005). *Ecosystems and human well-being: wetlands and water*, Washington, DC: World Resources Institute; Liqueite, C., Piroddi, C., Drakou, E. G., Gurney, L., Katsanevakis, S., Charef, A. and Egoh, B. (2013). Current status and future prospects for the assessment of marine and coastal ecosystem services: A systematic review. *PLoS One* **8**, e67737.

and slowly release it, as a sponge does, which allows these wetlands to moderate flows and reduce flood peaks and flood damage in water courses downstream (Fritz et al., 2018; Lane et al., 2018). Headwater wetlands also recharge and replenish the groundwater table (Lane et al., 2018).

Coastal wetlands, both salt marshes and mangrove swamps, act as barriers for coastal defense. They attenuate wave energy and floodwaters and stabilize the shorelines in estuarine and marine ecosystems (Shepard et al., 2011; Leonardi et al., 2018; Reed et al., 2018). However, sufficient sediment supply is required to maintain the coastal defense function of coastal wetlands (Boesch et al., 1994).

Wetland ecosystems purify water by filtering out sediments, nutrients, wastes and some pollutants (Verhoeven et al., 2006; Reddy and DeLaune, 2008). Some wetlands are even designed and constructed to treat nutrient-enriched waters in urban, industrial or agricultural settings (Kadlec and Wallace, 2009).

Wetlands are also key ecosystems for the control of climate change (Moomaw et al., 2018). Over millennia, wetlands, especially coastal wetlands and boreal peatlands, have sequestered and stored large quantities of carbon as organic enriched sediments and peat, making them key carbon sinks with the potential for mitigating the impacts of climate change (Mitsch et al., 2013; Sjogersten et al., 2014). However, methane, an important greenhouse gas, is also released from some wetlands (Bridgham et al., 2013; Mitsch and Gosselink, 2015).

Many wetlands provide significant cultural services, such as opportunities for ecotourism, recreation and even spiritual and aesthetic enjoyment. Consider mangrove swamps. They were once avoided as zones of danger, darkness and disease, at least to western eyes (Friess, 2016). Today, mangrove swamps not only provide recreation opportunities for tourists, such as birdwatching and nature enjoyment (Uddin et al., 2013), they also give spiritual and cultural meaning to those who visit them (Thiagarajah et al., 2015).

Threats to Wetlands

Wetlands face many threats, including drainage and conversion, changes in their hydrology, excess nutrients, invasive species and climate change.

The conversion or drainage of wetlands is the most important threat facing wetlands (Junk et al., 2013; van Asselen et al., 2013). Between 54% and 57% of natural wetlands are estimated to have been lost since 1700 AD, with a more rapid loss of between 64% and 71% since 1900 AD (Davidson, 2014). The most significant causes for these losses of wetlands are the expansion of arable land and the expansion of urban land, although the construction of dams, dykes and other infrastructure is also an important cause in some regions (van Asselen et al., 2013). Large urban population centres are often present in deltas and floodplains, which explains why wetland losses to urbanization are high. Some of the natural wetlands that are converted to agriculture, such as rice paddies, still provide some ecosystem services such as flood control and faunal habitat (Verhoeven and Setter, 2010; Gopal, 2013). Institutional and regulatory frameworks, such as the use of subsidies to convert natural wetlands to cropland, are also still responsible for substantial wetland losses in some regions (van Asselen et al., 2013).

The remaining wetlands are often affected by changes in flooding regimes (Junk et al., 2013). For instance, water control structures along rivers reduce species diversity in remaining wetlands downstream (Nilsson et al., 2005). In coastal wetlands, ditching and canalizing does not necessarily drain the wetlands, but they can lead to saltwater intrusion and consequent vegetation shifts (Gedan et al., 2009).

Although wetlands are valued for their ability to filter nutrient-enriched waters, excess nutrients can shift vegetation and ecosystem processes, especially in historically infertile ecosystems (Moore et al., 1989; Verhoeven et al., 2006). For instance, in the subtropical Everglades wetlands in the United States, oligotrophic marshes that have received nutrient-enriched agricultural runoff shift their species composition from sawgrass to cattail (McCormick et al., 2011). Atmospheric pollution also impacts infertile wetland ecosystems. For instance, peatlands subject to nitrogen-enriched atmospheric pollution shift toward non-peat accumulating wetlands (Bubier et al., 2007). Depending on their landscape position, wetlands may also receive high loads of contaminants from nearby land uses. For instance, wetlands that receive pesticide-enriched runoff from intensive agricultural land have higher incidences of limb malformations in the amphibians that breed there (Mann et al., 2009).

Invasive species, both animals and plants, are also a serious threat to wetlands by changing dominance of wetland species, the structure of their habitat and the food webs (Shaffer et al., 1992; Zedler and Kercher, 2004). A quarter of the most invasive species of plants are found in wetlands (Zedler and Kercher, 2004). Examples in wetlands include common reed (*Phragmites australis*) in wetlands of temperate North America, salt-cedar (*Tamarix* spp.) in floodplain wetlands of arid southwestern North America, and water hyacinth (*Eichhornia crassipes*) in tropical to sub-tropical wetlands outside of its native South American range (Shafroth et al., 2005; Villamagna and Murphy, 2010; Hazelton et al., 2014).

Climate change is also threat to wetlands, since it has the potential to change the water balance and the consequent flooding regime of wetlands (Mitsch et al., 2013). More importantly, climate warming could lower the water tables in peatlands and transform these peatlands from carbon sinks to sources of greenhouse gases, causing further climate warming (Moomaw et al., 2018).

Coastal wetlands are also threatened by sea level rise associated with climate change (Kirwan and Megonigal, 2013). However, recent research indicates that coastal wetlands can keep up with sea-level rise, if sufficient space is available for these coastal wetlands to migrate upgradient and inland as sea levels rise, and if they receive sufficient sediment supply (Schuerch et al., 2018).

However, where shoreline hardening inland restricts their upward and inland migration, coastal wetlands may be caught in a “coastal squeeze,” which limits their ability to migrate with sea level rise (Torio and Chmura, 2013).

Wetland Conservation and Restoration

Efforts to conserve and to restore wetlands have grown over the past half century. Arguments for their conservation are often based upon their high utilitarian value through the ecosystem goods and ecosystem services that they provide. But they are also intrinsically valuable as habitat for unique and often threatened biota. Both the utilitarian values and intrinsic values of wetlands should be considered in wetland conservation.

The Ramsar Convention on Wetlands was adopted in 1971 as an international treaty to promote the conservation and wise use of wetlands and their resources. Over 2300 wetlands, covering 2.5 million km² in 170 countries, are now designated as internationally important wetlands under this treaty (Ramsar Convention on Wetlands, 2018). Some countries, such as the United States and Canada, have few Ramsar sites, but they conserve wetlands through other protection systems. Nevertheless, only 10% of inland wetlands globally have protection status either as Ramsar sites or as other protected areas (Reis et al., 2017). Furthermore, few of these protected areas have safeguards to maintain their hydrology, their sediment dynamics and their water quality, upon which they depend (Reis et al., 2017). Wetland conservation must consider these key processes in order to retain the extent, quality and function of conserved wetlands.

A total of 73 countries have implemented national policies for wetland conservation (Ramsar Convention on Wetlands, 2018). The strength of these policies vary greatly, from countries with paper-only policies to countries with stringent policies where wetland loss is offset by the creation or restoration of wetlands elsewhere, as is attempted in the United States. Wetlands International (www.wetlands.org) is the primary non-governmental organization involved in the conservation of wetlands internationally, but national organizations operate in many countries toward the conservation of wetlands.

Wetland restoration or creation has increased substantially over the past half century as a strategy to mitigate the loss of wetlands, their ecosystem goods and services and their biodiversity (Darrah et al., 2019). However, data on the area of restored wetland are lacking in most regions. Restoration methods exist for several wetland types, including temperate swamps and marshes, bogs, vernal pools, floodplain wetlands, salt marshes and mangrove swamps (Broome et al., 1988; Quinty and Rochefort, 2003; Bosire et al., 2008; King et al., 2009; Calhoun et al., 2014; Biebighauser, 2015; Chimner et al., 2017). Further efforts are required to compile comprehensive restoration protocols across wetlands. Note that the biological structure and biochemical functioning of restored wetlands are lower than in natural wetlands nearby (Moreno-Mateos et al., 2012). This result, along with the high costs of wetland creation or restoration, suggest that the conservation and sound management of existing wetlands should take precedence over wetland creation and restoration, wherever possible. However, given the historical and current losses of wetlands, the restoration or creation of wetlands remains a useful strategy for wetland conservation.

Abstract

Ponds are abundant landscape elements that provide vital ecosystem services and contribute significantly to biodiversity. Despite their importance for human society, they are threatened habitats and their protection and conservation is often neglected in current national and international legislation. We summarize a number of key-aspects on pond ecology and biodiversity. In addition, we discuss current policy and highlight essential elements for the effective conservation of ponds.

Key Characteristics

Despite the large variety of ponds around the world, efforts towards their classification have been limited so far, with a few exceptions in Europe (see for example [Kalettka and Rudat, 2006](#)). In the broad sense, ponds are small (1 m^2 to 5 ha), natural or man-made shallow lentic waterbodies that permanently or temporarily hold water ([Biggs et al., 2005](#); [Céréghino et al., 2008](#)). They are abundant ecosystems that occur in virtually all biogeographical regions ([Holgerson and Raymond, 2016](#)). Global estimates suggest that ponds represent approximately 90% of the standing waterbodies in the world and comprise up to 30% of the standing water by surface area ([Downing et al., 2006](#)). Despite their relatively small individual size, ponds are important ecosystems because they support global biogeochemical cycles ([Cole et al., 2007](#); [Downing et al., 2008](#); [Holgerson and Raymond, 2016](#)), provide vital ecosystem services ([Ipbcs, 2018](#)), and strongly contribute to biodiversity ([Williams et al., 2004](#); [Davies et al., 2008](#)).

The creation of natural ponds involves processes such as glacial activity in temperate and polar regions, the formation of oxbow ponds in alluvial areas, and the erosion of bedrocks. Natural ponds also arise in landscape depressions that permanently or temporally fill with water, as well as in periodically inundated floodplains. Animal activity, such as dam construction by beavers ([Johnston and Naiman, 1990](#)) or wallowing of large mammals ([Ayeni, 1977](#)) can also lead to the creation of ponds. In addition to the vast number of natural ponds, a considerable proportion of ponds is of anthropogenic origin ([Chester and Robson, 2013](#)) and has been created to fulfill a variety of human demands including fish production, sediment retention, recreation, and water supply ([Biggs et al., 2017](#)). In addition, multiple cases of unintentional pond creation also exist. For instance, ponds have formed in bomb craters ([Vad et al., 2017](#)) or mining quarries ([Dolný and Harabiš, 2012](#)). Many man-made ponds are now surrogate habitats for species of which the natural habitat has been lost ([Chester and Robson, 2013](#); [Lemmens et al., 2013](#); [Hill et al., 2017a](#); [Oertli, 2018](#)). In recent years, urban ponds are increasingly appreciated for their contribution to biodiversity and ecosystem services in anthropogenic landscapes ([Oertli and Parris, 2019](#); [Hassall, 2014](#); [Hill et al., 2016](#)) ([Fig. 1](#)).

Ponds are closely connected to their surrounding environment. This is definitely the case with respect to their water supply, which directly or indirectly depends on groundwater, precipitation, river connection or surface run-off. However, it also holds for their interaction with the soil and other ecotopes. Consequently, pond characteristics tend to differ extensively between ponds, both across and within climatological regions. While part of the variation among ponds is determined by differences in geology, soil typology, hydrology and landscape position, variation between ponds can also result from differences in pond morphology and internal processes that determine physical and chemical conditions. Furthermore, ponds are highly dynamic ecosystems in which the relative importance of environmental variables—and their interaction—varies considerably over time ([Hassall et al., 2012](#)). Therefore, pond age and pond history may also impact the abiotic and biotic characteristics of an individual pond at a given time ([Sferra et al., 2017](#); [Fairchild et al., 2000](#)). Finally, human interaction and disturbance have also become important factors, determining the characteristics and functioning of pond ecosystems.

Ponds share many characteristics with lakes ([Søndergaard et al., 2005](#)) and the distinction between both types of habitats is rather gradual ([De Meester et al., 2005](#)). Nevertheless, typical ponds are clearly distinguishable from typical lakes based on several functional aspects ([Oertli et al., 2002](#)). First, they have a smaller volume to edge ratio, which leads to a higher proportion of littoral zone and a more profound interaction with the surrounding terrestrial environment. Second, resuspension of sediments and internal eutrophication are generally less profound in ponds than in lakes because ponds are less exposed to wind and mostly lack dense fish populations that resuspend sediments. Third, ponds are relatively shallow (typically $< 3 \text{ m}$), which facilitates the development of aquatic vegetation over their entire water surface area and prevents profound thermal stratification of the water

Fig. 1 Examples of different types of ponds. *Top left*: Temporary floodplain pan from Karingani Game Reserve in Mozambique. *Top right*: Temporary rock pool on top of an inselberg in Western Australia. *Lower left*: Farmland pond in Belgium. *Lower right*: urban pond in a city park in Brussels, Belgium. *Top left*: Courtesy of Tom Pinceel. *Top right*: Courtesy of Tom Pinceel. *Lower left*: Courtesy of Mariuxi Peso, *Lower right*: Courtesy of Kristien Brans.

column (Scheffer, 1998). Fourth, ponds mostly have a much smaller catchment area (Davies et al., 2008). Finally, ponds have a higher probability to periodically dry out because of their relatively small size and shallow depth.

Biodiversity and Community Dynamics

Ponds harbor a significant proportion of global freshwater biodiversity (Dudgeon et al., 2006; Strayer and Dudgeon, 2010) and are important habitats for biodiversity conservation (Céréghino et al., 2014; Oertli et al., 2010). Indeed, ponds are often characterized by relatively high levels of local biodiversity and frequently contain multiple rare and endangered species (Davies et al., 2008; Williams et al., 2004). However, ponds are especially valuable because of their disproportionately strong contribution to regional biodiversity (Biggs et al., 2005; Williams et al., 2004; De Bie et al., 2010), which can largely be attributed to high spatial community turnover (Hill et al., 2018a) and the occurrence of unique species that are specific to small lentic waterbodies (Davies et al., 2008). Species turnover between ponds results from variation in local habitat characteristics, such as hydroperiod, succession stage and trophic structure, as well as from stochasticity in community assembly (Jeffries, 1994; Hill et al., 2017b; Hassall et al., 2012; Chase, 2007). The ecological importance of ponds is thus not exclusively linked to the value of individual ponds, but rather related to a network of ponds at the landscape scale ("pondscape"). Finally, ponds do not only sustain aquatic and semi-aquatic organism groups, but also support a variety of terrestrial taxa, including birds (Davies et al., 2016).

Ponds are highly dynamic habitats that show profound variation in community composition and diversity within and across years. Within-year variation in community characteristics can mainly be attributed to seasonal variation in climatological conditions and variation in biotic interactions (Brooks, 2000; Black and Hairston, 1988). Many pond systems become unfavorable or at least sub-optimal environments for their inhabitants during a certain period of the year (Williams, 2006). In temperate regions, this period is often associated with winter conditions of low temperatures and low sunlight radiation. Primary productivity is strongly reduced under these conditions, which can lead to nutrient limitation for consumers. Given that many pond inhabitants are ectothermic organisms, low temperatures imply strongly reduced metabolic rates and low activity (Clarke and Johnston, 1999). In order to bridge unfavorable episodes, organisms tend to react to cues that precede these and either move away (e.g., migratory insects), enter a state of metabolic rest (e.g., fish hibernation) or produce resistant dormant stages (e.g., phyto- and zooplankton cysts). Upon the return of favorable conditions for growth and reproduction, "active life" is resumed and dormant stages develop. Often, development is triggered by specific cues and not all organisms join the active community at the same time (Brendonck and

De Meester, 2003). Through such temporal niche segregation, competitive and predatory interactions may be avoided and organisms can tune their presence to the availability of specific resources that ensure optimal population performance (Jocque et al., 2007) (Fig. 2).

For temporary pond inhabitants the temporal variation in habitat suitability is even more extreme as their habitats sporadically disappear altogether due to drying. Local climate (rainfall and temperature) and near-surface geomorphology largely determine the frequency, length and variation in length of filling events (together defined as the hydroregime) of temporary waters (Williams, 2006; Hulsmans et al., 2007). Temporary waters may dry out as frequently as several times a month or as rarely as once every couple of years (Blaustein and Schwartz, 2001). Some habitats like the temporary Australian Lake Eyre, for instance, only fill a few times every century (Magee et al., 1995). Still, when filled, these systems are often home to a diverse community of aquatic organisms.

The fauna of temporary ponds comprises permanent residents, that bridge the dry phase in situ as drought resistant stages, and temporary residents that move away when the water evaporates (Williams, 2006). The length of the inundation (i.e., the hydroperiod) largely characterizes the habitat and the physicochemical environment its fauna and flora is exposed to (Wellborn et al., 1996; Schwartz and Jenkins, 2000). Rainfall is often stochastic, especially in (semi-)arid regions, which results in unpredictable variation in the hydroperiod of temporary pools, even between inundations of the same habitat (Philippi et al., 2001; Tuytens et al., 2014). Therefore, the hydroperiod and variation in hydroperiod can be one of the main determinants of variation in species richness and community composition, among temporary waters but also among years (Holland and Jenkins, 1998; Brendonck et al., 2017; Vanschoenwinkel et al., 2013). Not only do longer inundations allow for more extensive temporal niche segregation, they also allow for more extensive community dynamics and an increased opportunity for arrival of dispersers (Jocque et al., 2007).

Many ponds show profound changes in biotic and abiotic characteristics over subsequent years. A considerable fraction of this inter-annual variability can be attributed to successional change (Hassall et al., 2012), although several other factors can also be important (but see Korhonen et al., 2010). The process of succession in ponds is relatively fast because of their relative small size and shallow depth. Succession rates largely depend on the extent of primary production and the input of allochthonous material (Khan and Ansari, 2005). Eutrophication promotes primary production and thus accelerates succession. Pond succession typically involves major changes in the plant community (Ray et al., 2001; Arts et al., 1990), with vegetation dominated by open water species in the early successional stages and dominance of helophytes in late successional stages. However, pond succession also affects the community characteristics of other organism groups (see for example Fairchild et al., 2000; Raebel et al., 2010; Ruhí et al., 2011), and different taxa respond differentially to succession (Hassall et al., 2012). The rate of succession is generally faster in more shallow ponds because shallow water promotes helophytes of which the biomass is decomposed slower compared to

Fig. 2 Examples of pond inhabitants. Upper left: *Branchinella longirostris* is a dominant competitor in temporary rock pools across Western Australia. Upper right *Nothobranchius* killifish, such as *Nothobranchius furzeri*, are top predators in temporary ponds across Southeastern Africa. Like many zooplankton species, they bridge dry phases as resistant dormant eggs. Lower left: *Daphnia magna*, an important phytoplankton grazer in many ponds. Lower right: Courtesy of Robby Stoks.

organic material originating from submerged aquatic vegetation. In contrast, periodic drying slows down succession because it facilitates the remineralisation of organic material in pond sediments. Pond succession does not only affect biotic communities, but can also alter the chemical conditions of the water. Because succession gradually reduces the depth and volume of ponds, the end point of pond succession involves filling and terrestrialization, which finally results in the loss of ponds. Local biodiversity is expected to be highest in ponds at intermediate successional stages, but early and late successional communities have an important contribution to regional biodiversity (Hassall et al., 2012). Regional diversity can thus only be maximized by considering the dynamic nature of ponds with ponds in different successional stages.

Threats

Lentic freshwater systems belong to the most endangered ecosystems on the globe (Sala et al., 2000; Strayer, 2010; Carpenter et al., 2011; Gozlan et al., 2019). Habitat degradation and habitat destruction are considered major anthropogenic factors affecting the ecological integrity of ponds (Dudgeon et al., 2006; Strayer and Dudgeon, 2010). Additional concern arises from climate change (Moss, 2017). Ponds are especially vulnerable to environmental degradation because of their small size and volume (Boothby, 2003; Biggs et al., 2005).

Intensified land use practices and excessive application of fertilizers on agricultural lands have resulted in enhanced nutrient input in many regions on earth. As a result, an increasing number of pond ecosystems currently suffers from anthropogenic eutrophication (Smith and Schindler, 2009). Ponds are especially vulnerable to eutrophication (both phosphorus and nitrogen) because of their relatively small volume (Brooks, 2009; Biggs et al., 2005) and the intense interaction between the sediment and the water column, which facilitates internal eutrophication (Smolders et al., 2006). Eutrophication increases the primary productivity of pond ecosystems and can eventually cause a shift from a clear macrophyte dominated state to a turbid phytoplankton dominated state (Scheffer et al., 1993). Such state shifts are often difficult to reverse (Scheffer and Carpenter, 2003) and have a negative impact on biodiversity and the provisioning of ecosystem services (Hilt et al., 2017; Folke et al., 2004). Eutrophication also promotes toxic cyanobacteria blooms (Anderson et al., 2002). Eutrophicated ponds typically have low levels of biodiversity because of the absence of dense submerged vegetation. Submerged vegetation promotes aquatic biodiversity (Jeppesen et al., 1998; Hansson et al., 2010) by enhancing physical habitat complexity, increasing food availability and providing refuges for prey against predation (Kornijów et al., 1990; Warfe and Barmuta, 2004).

Land-use intensification has led to dramatic losses of ponds worldwide (Curado et al., 2011; Davidson, 2014). In Western Europe, for instance, approximately 50% of all ponds has been lost over the past century (Hassall, 2014). This is problematic because ponds typically form a pond network ("pondscape") in which individual pond communities interact via dispersal of organisms (e.g., the metacommunity framework, see Leibold and Chase, 2017). The loss of ponds can have direct negative effects on regional diversity by reducing the amount of suitable habitats (both the number of ponds and the total habitat area) (Gledhill et al., 2008), but can also reduce local and regional pond biodiversity through alteration of extinction-colonization dynamics by reducing landscape connectivity (Horváth et al., 2019).

Small freshwater bodies, such as ponds, are severely affected by climate change (Gozlan et al., 2019). Because of their typically small volume, temperature conditions tend to vary with atmospheric temperatures. Therefore, many pond systems experience more extreme temperatures and increasing daily temperature fluctuations (Carpenter et al., 1992; Stoks et al., 2014). While temperature changes may directly cause physiological stress to inhabitants (Jackson et al., 2016), altered temperatures may also indirectly affect organisms by, for instance, changing the solubility of gasses (e.g., oxygen) (Ficke et al., 2007). Increased temperatures are also associated with increased evaporation rates. For isolated ponds, increased evaporation results in higher concentrations of dissolved compounds including salts (Nielsen and Brock, 2009), and for temporary ponds it may result in early drying (Moss, 2012; Tuytens et al., 2014). Current climate change projections predict that rainfall will be reduced and more erratic in many regions (IPCC, 2014). Especially for temporary ponds, which are often directly dependent on rainfall for their inundation, this would imply changes in inundation regimes. Combined with higher evaporation rates due to increased temperatures, inhabitants of these systems would be faced with unpredictable drying and become increasingly time-stressed to complete the aquatic stages of their lifecycle (Moss, 2012). Climate change is at least partly caused by increasing greenhouse gas emission levels (IPCC, 2014). Following the industrial revolution in the 1750s, concentrations of carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O) have overall increased by 40%, 150%, and 20%, respectively (status in 2011; IPCC, 2014). While atmospheric CO₂ levels were around 278 ppm in 1750, currently the concentration is typically at 406 ppm and a further increase to up to 900 ppm is predicted by 2100 (Meinshausen et al., 2011). Although effects of increased CO₂ levels were long neglected for freshwaters, they may be far reaching and result, for instance, in acidification of aquatic systems and a higher carbon availability in aquatic food webs (Van de Waal et al., 2010). Combined with eutrophication, higher carbon availability could, in turn, directly increase phytoplankton productivity (Schippers et al., 2004).

Legislation and Conservation Management

With the definition of 17 sustainable development goals by the United Nations in 2015, the protection and the restoration of aquatic habitats were put high on the agenda (www.un.org/sustainabledevelopment). However, despite the high value of ponds for biodiversity conservation and the provisioning of vital ecosystem services, ponds are largely neglected in current national

and international policies and strategies (Biggs et al., 2017). In Europe for example, the Water Framework Directive is implemented to protect water quality of freshwater and shallow coastal waters. Yet in practice the focus lies almost entirely on river systems and large lentic waterbodies (> 50 ha) (EC, 2000). Unfortunately, the lack of direct legislative protection for ponds is also prevalent in most other regions, including Australia, Asia, and North-America (but see Hill et al., 2018b). Nature conservation legislation is currently the most important tool for the protection of ponds and their biodiversity (for example the Habitats Directive at EU-level and the Ramsar Convention at international level) (Hill et al., 2018b). Such legislations have definitely been successful, but their effectiveness is also limited because they largely focus on the protection of individual sites. Current knowledge on the drivers and dynamics of pond biodiversity suggests that legislations targeting pondscapes, rather than individual ponds, will be more effective in promoting biodiversity. This largely stems from the high spatial community turnover between ponds and the high temporal variation in the conservation value of individual ponds (Hassall et al., 2012). A focus on the pondscape level also allows improvement of the ecological connectivity of the landscape, which might be especially relevant in human-dominated landscapes that have been subjected to a profound loss of ponds, such as agricultural and urban areas.

Pond management is increasingly needed to conserve and enhance biodiversity. This is definitely the case in human dominated landscapes where biodiversity strongly depends on human interference (Biggs et al., 2005). Current restoration programs typically aim at the restoration of degraded ponds by promoting a clear-water-state with profound submerged vegetation (Usio et al., 2017; Sayer et al., 2012). Nevertheless, scientific evidence for the effectiveness of specific pond restoration measures based on biodiversity conservation is scarce. Empirical investigation suggests that adverse external influences to pond ecosystems from the surrounding environment can be mitigated most efficiently at small spatial scales (Declerck et al., 2006). For example, the presence of buffer strips with shrub vegetation around the shoreline can drastically reduce the input of nutrients, sediment run-off and pollution from the catchment (Joniak et al., 2017). Other management interventions include the removal of surrounding woody vegetation to increase insulation and promote the development of submerged aquatic vegetation (Sayer et al., 2012), and dredging to reset the successional stage of late-successional ponds (Hassall et al., 2012). Additional measures, such as changing the pond morphology or hydroperiod, might be relevant to target specific conservation goals (but see Williams et al., 2010a,b; Oertli and Parris, 2019).

Importantly, pond restoration measures should always be taken with care as some interventions might negatively affect local populations. The presence of regional species pools and the degree of habitat connectivity should definitely be considered prior to any radical management measure. Management at the pondscape level is the most effective approach to conserve biodiversity because it can promote landscape connectivity and can enhance habitat diversity (Oertli, 2018; Oertli and Parris, 2019; Hassall et al., 2012). Conservation programs targeting pondscapes, rather than individual ponds, also allow consideration of the dynamic character of pond ecosystems. With respect to this, the creation of new ponds has been proposed as an effective biodiversity conservation approach, especially in regions that have experienced a profound loss of ponds (see for example the Million Ponds Project, Williams et al., 2010a). Pond creation does not only enhance ecological connectivity of the landscape, but is also beneficial for regional diversity by providing early successional habitats. The latter might be especially relevant in regions that are dominated by late successional ponds since multiple studies highlight the importance of conserving a mosaic of pond successional stages within pondscapes. Resetting the successional stage of a subset of late successional ponds in the pondscape by dredging can be an effective measure to promote regional diversity in regions where the possibilities to create new ponds are limited.

Abstract

There are ~304 million freshwater lakes world-wide with the highest concentration, area, and perimeter of lakes located within boreal and arctic latitudes. The seven main formation processes of lakes are tectonic activity, volcanic activity, glacial activity, fluvial action, aeolic action, anthropogenic action, and marine action. Lakes are generally characterized by low flow velocity and relatively low inflows and outflows. The primary parameters used to describe geomorphologic characteristics include lake length, lake width, lake depth, direction of major axis, shoreline length, lake area, lake volume, insulosity, and watershed to lake area/volume. Approximately 45% of photosynthesis on earth occurs in aquatic environments and photosynthesis supplies the primary source of organic matter for the growth and metabolic demand of all organisms in lakes.

Cultural eutrophication is thought to be the most widespread stressor in natural lakes. After eutrophication, acidification is the most important threat and stress factor for lakes. Above all, aquatic ecosystems are very vulnerable to climate change

which influences the physical, chemical, and biological structure of lakes. These influences include fluctuating water levels, increased water temperature, shorter ice-cover periods, invasion of nonindigenous animal and plant species from tropical and subtropical regions, and structural changes in catchment areas.

The value of biological diversity in freshwater lakes and the need for its conservation is becoming more important world-wide. However, the challenges involved with the conservation of freshwater lakes are great. It is often difficult to decide what management action to implement and what will be most effective. However, positive conservation action has brought real and sustained benefits across scales, from local to global, via a variety of mechanisms.

Introduction

The ability of lakes to retain, store, clean, and evenly provide water means they are an essential component of the hydrological and biogeochemical water cycles, and, as such, influence many aspects of ecological relationships and human well-being (Lehner and Döll, 2004). Lakes are generally defined as permanent bodies of still water (i.e., lentic water bodies) without direct connection to an ocean. They are formed by water filling geologic depressions (e.g., tectonic, volcanic, water or wind erosion) or by water being impounded behind a natural dam (e.g., glacial moraine, landslide) (Uhlmann et al., 2011). The size and shape of lakes is directly related to how they originated and how long they have been in existence. The resulting morphology of lakes (e.g., surface area, depth, shape, shoreline), regardless of how they were formed, determines their hydrological and biological characteristics (Kalff, 2002). Characteristics of lakes are also closely associated with characteristics of their drainage basin (Wetzel, 2001). Slope, soil, and vegetation influence the quality of water entering lakes (e.g., turbidity, organic matter). The area of drainage basins relative to the area of lakes is generally < 10:1 (Uhlmann et al., 2011).

There are ~8 million natural lakes world-wide with surface areas of > 1 ha (Ryanzhin et al., 2001) and about 304 million lakes ≥ 0.1 ha that cover 4.2 million km². (Downing et al., 2006; Downing and Duarte, 2013). The majority of them are freshwater lakes. This article provides broad insight to the contribution of lakes to the freshwater biome.

Biogeography

The highest concentration, area, and perimeter of lakes are located within boreal and arctic latitudes (i.e., 45°–75°N) while abundance of lakes is lower at southern latitudes where continental area is also lower (Verpoorter et al., 2014). Also, the total number, area, and perimeter of lakes decrease with increases in elevation (Verpoorter et al., 2014). Eighty-five percent of lakes, 50% of lake area, and 50% of total lake perimeter are located at elevations lower than 500 m above sea level.

Lakes of Europe

There is a great deal of variability in the characteristics of lakes in Europe. This variability is primarily a result of gradients in climate, geological history, land use, and atmospheric deposition, generally along a north–south axis. Lakes are also abundant in Europe, but similarly, numbers also decline from north to south (Weyhenmeyer et al., 2009). Stressors affecting lakes in Europe include climate change, intensive land use, increasing industrial activities, overfishing, invasive species, and atmospheric deposition of acids, metals, and organic pollutants (Weyhenmeyer et al., 2009).

A major issue facing lakes throughout Europe is decreasing quality of water resulting from human-induced increase of nutrient concentrations leading to heavy algal blooms. European countries are addressing these stressors by implementing the European Water Framework Directive to protect and enhance aquatic ecosystems and promote sustainable water use across Europe (Carvalho et al., 2019).

Lakes of Asia

The geological history and complex geomorphology of Asia has resulted in a large diversity of natural lakes that vary in age, area, depth, hydrology, water quality, and biodiversity (Gopal and Ghosh, 2009). For example, Asia has the world's largest lake (Caspian Sea), the oldest and deepest lake (Lake Baikal) as well as at the highest (~6000 m) and lowest elevations (Dead Sea, > 400 m below sea level), and with the highest salinity (> 400‰). Most of the natural lakes originated from tectonic activities over the past several million years.

This continent supports over half of the global human population, with consequent pressures on inland waters (including lakes), and a very significant part of the world's biological diversity (Dudgeon et al., 2006). Many lakes in Asia have been modified by human activities to create fishponds, including the introduction of exotic species (Dudgeon, 2000). As a result, there has been a loss in biological diversity and homogenization of the regional biota. Human livelihoods are a paramount consideration in Asia so reversal of these trends will be difficult (Gopal, 2005).

Lakes of Africa

North Africa

North Africa has considerable inland water resources with specialized aquatic flora and fauna. Lake environments are affected by conditions ranging from subhumid to arid so diversity of aquatic life shows much variation (Ramdani et al., 2009). Natural water resources like lakes have significant cultural importance in this area because of the general scarcity of water. Disturbance activities caused by agriculture and development have resulted in modified systems (Fouchy et al., 2019). Without active management that includes traditional methods as well as new innovations, these changes in natural systems will be exacerbated by climate change.

African Great Lakes

The African Great Lakes consist of large, deep rift valley lakes (e.g., Malawi and Tanganyika) and shallower lakes between the Eastern and Western Rifts (e.g., Victoria) (Coulter et al., 1986). Current management problems include over-fishing, increased input of sediment and nutrients, and, in the case of Lake Victoria, loss of endemic fish species and the proliferation of the introduced water hyacinth (*Eichhornia crassipes*). The great biological diversity in these lakes, and the recent loss of much of this diversity from Lake Victoria, present opportunities to examine the relationships between community structure and ecosystem functioning in natural settings (Bootsma and Hecky, 2003).

Lakes of Australia and New Zealand

Although these countries have different water resource concerns (i.e., generally dry Australia vs. wet New Zealand) many of their lakes have experienced similar changes since European colonization, including modified watershed land use, and the associated changes in hydrology, as well as deterioration of water quality (Brookes and Hamilton, 2009; Abell et al., 2019). Lakes in both countries reflect the major regional geological processes, hydrology, and climate leading to tremendous diversity of lakes. Glacial lakes are the most common lakes in New Zealand, and are generally the deepest lakes due to their formation in former glacial valleys.

Lakes in Australia and New Zealand have played important roles in ancient and recent cultural history (Brookes and Hamilton, 2009). Aboriginal and Maori settlements have focused around lakes and rivers. Subsequent European colonization drastically altered the landscape in both countries leading to a general deterioration of water quality. Nutrients, cyanobacteria, and pathogens are the principal water quality concerns (Verburg et al., 2010; Weeks et al., 2015). The main impact of human settlement on the area's shallow freshwater lakes, brackish lakes and lagoons, and deep lakes has been eutrophication along with changes in biological diversity, the introduction of nonnative species, and an increase in the vulnerability of lakes to regime shifts (Schallenberg and Sorrell, 2009; Schallenberg, 2019). Agriculture-related stressors such as sedimentation, nutrient enrichment, and flow regime changes are most pervasive, whereas other stressors either remain more localized (e.g., salinization and mining) or will be of growing concern in coming decades (e.g., climate change) (Matthaei and Piggott, 2019). Climate change will probably intensify stresses related to water scarcity due to hotter temperatures and lower, more variable rainfall.

Lakes of North America

North America contains 8 of the 20 largest lakes of the world, defined as having more than 10,000-km² surface area, all of which were formed by glaciers (Kalff, 2002). Five of these "Great Lakes" are in the Laurentian system, that is, the St. Lawrence River watershed (Superior, Huron, Michigan, Erie, and Ontario), and three others lie entirely in Canada (Great Bear, Great Slave, and Winnipeg) (Hansen et al., 2010).

The last continental glacier left North America with a large number of freshwater natural lakes that extended over the northern half of the continent, mostly north of 40° north latitude (Cole, 1994). Natural lakes are important resources throughout North America and contribute substantial economic benefits (Hansen et al., 2010). Recreational, commercial, and subsistence fisheries are among the most important social and economic values of natural lakes in North America.

Lakes of South America

South America is predominantly a rivers continent (Llames and Zagarese, 2009). As such, many floodplain lakes originate from rivers; particularly, from the Amazon, Orinoco, and Paraná-Plata rivers, which rank among the largest river systems of the world. As a result, the number of typical lakes is relatively small. The factors that determine the diversity of these lakes include geography, geomorphology, and climate.

Most Andean lakes were formed by tectonic activity, volcanism, or glaciers (Llames and Zagarese, 2009). Tectonic and volcanic events were most active in arid regions. Consequently, there are fewer tectonic lakes than glacial lakes in the Andes. Inland lowland lakes tend to be shallow fluvial lakes associated with floodplains of the large rivers of the region. The majority of these floodplains retain most of their natural hydrological characteristics.

Loss of habitat for indigenous plants and animals was the main concern identified for all South American lake ecosystems (Barletta et al., 2010). It may be caused by damming of rivers, deforestation, water pollution, mining, poor agricultural practice, or inadequate management practices. The biological diversity associated with lakes in South America is far from fully known. Continuing loss of habitat for associated species may result in losses of biological diversity before the full diversity of species is known.

Lakes of Antarctica

Despite temperatures well below the freezing point, the Antarctic continent possesses a wide variety of lakes that contain liquid water throughout the year, making them an oasis for life in what would otherwise appear to be an uninhabitable environment (Priscu and Foreman, 2009). Lakes in Antarctica are distributed on maritime islands, along the margins of the continent in ablation regions, and subglacially, beneath the ice sheet. More than 150 lakes exist beneath the ice sheet, many of which may be connected by large subglacial rivers. These lakes may harbor microbial ecosystems isolated from the atmosphere for as long as the continent has been glaciated (i.e., 20–25 million years).

Most of the 17 lakes on ice-free Signy Island lie in the valleys and plains of the narrow, coastal lowland which is usually snow free during the summer (Priscu and Foreman, 2009). The Schirmacher Hills contain several freshwater lakes formed by ice erosion and relict saline lakes formed as a result of the isolation of sea inlets and lagoons. These lakes are fed by melt water from snow beds and ice slopes during the summer. The lakes in Larsemann Hills may have formed from the exposure of basins after the retreat of the continental ice cap or after isolation due to the isostatic uplift following deglaciation.

Following the retreat of the continental ice sheet on the Vestfold Hills about 12,000 years ago, isostatic rebound occurred at a faster rate than sea level rise (Priscu and Foreman, 2009). As the land rose, it cut off fjords and trapped pockets of seawater, creating lakes. The lakes closest to the ice sheet are typically fresh, while those closer to the coast tend to be saline or hypersaline. Over 200 water bodies occur in the Bunger Hills, ranging in size from small, shallow ponds that freeze to the bottom during winter, to Algae Lake, one of the largest and deepest surface freshwater lakes in Antarctica (Priscu and Foreman, 2009). The McMurdo Dry Valleys contain eight relatively large lakes, all of which have permanent ice covers ranging in thickness from ~4 to 7 m (Priscu and Foreman, 2009). Coastal lakes and ponds are distributed around the margins of the Antarctic continent, and are particularly abundant around the ice free areas of McMurdo Sound (Priscu and Foreman, 2009).

Lakes of the Arctic

A major feature of Arctic landscapes is their large number of lakes and ponds, which in some regions can cover up to 90% of the total surface area (Pienitz et al., 2008). Although lakes in the Arctic are formed by nearly all of the processes that lakes are formed by, including the major categories of volcanic, glacial, and tectonic forces, most lakes in this area are formed by thermokarst processes (i.e., thermal erosion of permafrost soils) (Kling, 2009; Rautio et al., 2011). A feature of Arctic lakes is their low biological diversity of aquatic plants and animals, many of which are specialized toward extreme cold, low energy supply, and oligotrophy (Vincent et al., 2013).

Despite their generally isolated geographic locations, the freshwater lakes of the Arctic are subjected to a wide spectrum of environmental stressors (Schindler and Smol, 2006). High-latitude regions are especially sensitive to the effects of recent climatic warming. The depletion of stratospheric ozone over the north, together with the clarity of many Arctic lakes, renders them especially susceptible to damage from ultraviolet radiation. In addition, the long-range atmospheric transport of pollutants has led to elevated concentrations of many persistent organic pollutants (e.g., insecticides, which have never been used in Arctic regions) and other pollutants (e.g., mercury). Rapid development of gas and oil pipelines, mining for diamonds and metals, increases in human populations, and the development of all-season roads, seaports, and hydroelectric dams will also stress northern aquatic ecosystems.

Hydrologic and Geomorphologic Characteristics

The seven main formation processes of lakes are tectonic activity, volcanic activity, glacial activity, fluvial action, aeolic action, anthropogenic action, and marine action (Bek et al., 2019). Lakes are generally characterized by low flow velocity and relatively low inflows and outflows. Vertical stratification appears in deep lakes, while shallow lakes are considered well mixed in the vertical axis (Lewis, 2009). The main hydrodynamic processes in lakes are inflows and outflows, wind shear, vertical circulation, thermal stratification, and gyres and seiches.

The primary parameters used to describe geomorphologic characteristics include lake length, lake width, lake depth, direction of major axis, shoreline length, lake area, lake volume, insulosity, and watershed to lake area/volume (Timms, 2009).

Cael et al. (2017) estimated the volume of Earth's lakes to be 199,000 km³ (95% confidence interval 196,000–202,000 km³). This volume implies an overall mean depth (defined as total volume divided by total area) of 41.8 m. Lake depth has been used for decades as the best estimator of the sensitivity of lakes to nutrient loading (Vollenweider, 1975) and has been proven to be a reliable predictor for primary production and lake transparency (Canfield and Bachman, 1981). The existence of many shallow lakes indicates a large percentage of lakes could be susceptible to eutrophication via nutrient loading with increasing primary production and decreasing transparency.

Biological Characteristics

Photosynthesis is the biological conversion of light energy to chemical bond energy that is stored in the form of organic carbon compounds (Falkowski and Raven, 2013). Approximately 45% of photosynthesis on earth occurs in aquatic environments and

photosynthesis supplies the primary source of organic matter for the growth and metabolic demand of all organisms in lakes (Field et al., 1998; Falkowski and Raven, 2013). Photosynthetic organisms are the primary producers in lake ecosystems (e.g., cyanobacteria, algae, macrophytes) (Uhlmann et al., 2011). The biomass of primary producers is eaten by primary consumers (i.e., animals, from aquatic protozoa to many species of freshwater fish).

The resulting food webs are important characteristics of lake communities (Post et al., 2000). They influence community structure, ecosystem function, and contaminant concentrations in top predators. Geology, hydrology, and land-use have strong influences upon the lake community food web (Allan and Johnson, 1997). A variety of processes at multiple trophic levels create linkages among terrestrial, pelagic, and benthic energy pathways in lake food webs (Schindler and Scheuerell, 2002). Thus food webs provide an important conceptual link between population and community ecology in lakes (Woodward and Hildrew, 2002). Traditional models of lake food webs emphasized the importance of pelagic primary production. However, terrestrial and benthic primary production are equally or even more important than pelagic primary production for consumers in lakes (Solomon et al., 2011).

Plant Communities

Lake area, altitude, trophic state, and water quality have been found to be good predictors of macrophyte species richness for lakes (Murphy, 2002). Among aquatic macrophytes, there are emergent plants such as reeds (Gramineae), submerged vegetation such as milfoil (*Myriophyllum* spp.), and floating-leaved species such as water lilies (Nymphaeaceae) (Uhlmann et al., 2011). Some of the algae are filamentous; others are unicellular or grow in colonies. The richest world hotspots for aquatic macrophyte diversity all lie in the Neotropics (Murphy et al., 2019).

Loss of aquatic vegetation is accelerating in lakes throughout the world, especially submerged aquatic vegetation and particularly in lakes with an area larger than 50 km² (Zhang et al., 2017). Major threats to the survival of lake vegetation include eutrophication, algal blooms, land reclamation, aquaculture cultivation, and global climate change.

Animal Communities

Benthic Invertebrates

Benthic invertebrates are an abundant and diverse group of aquatic animals that are found on or in submerged substrates of lakes (Chaloner et al., 2009). Benthic invertebrate fauna includes representatives of nearly all animal phyla. However, aquatic insects are the most species-rich and abundant group of benthic invertebrates. The shallow littoral zone of lakes typically supports a more diverse invertebrate fauna than deeper water because of higher habitat heterogeneity, more abundant resources, and generally more favorable oxygen conditions. As participants in lacustrine food webs, benthic animals consume phytoplankton, aquatic plants, animals, bacteria, and detritus (Strayer, 2009). Benthic invertebrates are an important food resource for most freshwater fishes and are vital for decomposition of organic materials. Also, large populations of birds, bats, spiders, and other predators are drawn to lakes to feed on benthic animals, including emerging insects (Strayer, 2009).

Mammals

Although numerous mammals are associated with freshwaters and rely on wetland or aquatic vegetation for foraging (e.g., beavers [*Castor* spp.]) (Halley et al., 2012), very few depend on lakes exclusively. Baikal seals (*Pusa sibirica*) are endemic to Lake Baikal in Southern Siberia, Russia, are found only in this lake and connecting rivers, and are the only seals that live primarily in a freshwater lake (Miyazaki, 2018).

Other seals that live in freshwater include subspecies of ringed seals (*Pusa hispida*). The Ladoga seal (*Pusa hispida ladogensis*) is found entirely in Lake Ladoga in northwestern Russia and the Saimaa ringed seal (*Pusa hispida saimensis*) is found in Lake Saimaa, Finland (Sipilä and Hyvärinen, 1998). Colonies of harbor seals (*Phoca vitulina*) live in some lakes, such as Iliamna Lake, Alaska (Boveng et al., 2018) and the Ungava seal (*Phoca vitulina mellonae*) in Lacs des Loups Marins, Petit Lac de Loups Marins, and Lac Bourdel in northern Quebec (Seal, 2018).

Birds

Water birds provide a range of important ecosystem services associated with lakes (Whelan et al., 2008; Green and Elmberg, 2014). “Cultural services” such as providing human recreation, and “provisioning services” such as harvest for meat or feathers, have been in play throughout human history and continue to be important among cultures (Millennium Ecosystem Assessment, 2005; Wenny et al., 2011). “Regulating services” such as pest control, and “supporting services” such as maintaining connectivity for plants and invertebrates in isolated lakes by acting as vectors for dispersal, have received less attention but are also important.

Human influences on lakes can greatly alter the numbers and diversity of water birds (O’Connell, 2009). The total number of water birds on Earth is in decline, and many water bird species are threatened with extinction, although these declines are more acute in some parts of the world than others (Wetlands International, 2014). This will eventually result in reductions of their

positive ecological functions. The decline of water bird populations is likely to have significant negative consequences for lake ecosystems (Şekercioglu et al., 2004).

Fish

The number and diversity of fish species present in lakes generally increases with lake size in response to increases in habitat diversity (Matuszek and Beggs, 1988; Kalff, 2002). Species richness also responds to spatial, physical, chemical, and connection characteristics of lakes during their formation and development (Hansen et al., 2010). As a result, characteristic assemblages of fish are associated with specific type of lakes (e.g., cold water, cool water, warm water).

Recreational use of fisheries tends to predominate in lakes, especially in North America, but commercial and subsistence fisheries are also important uses of fish (Hansen et al., 2010). Recreational fisheries tend to rely on angling as the preferred method for securing fish. Commercial and subsistence fisheries rely on a greater variety of capture methods, including gill netting, trap-netting, angling, long-lining, and spearing.

Commercial Uses

Fisheries

Commercial fisheries in fresh water lakes have declined throughout Europe (Dill, 1993; Cowx, 2015). After slow expansion through the 1950s–1980s, catches have declined steadily over the past 25 years, more so in the north and west than in Eastern countries. For example, even though the commercial harvest of fish in fresh waters in Central and Eastern Europe (CEE) is declining, it continues to contribute to the livelihood of a large number of people (Aps et al., 2004). The total freshwater fish catches of all CEE countries decreased over 27% during the last decade of the 20th century.

Commercial fishing was an important industry during the settlement and development of the Laurentian Great Lakes region in North America (Brenden et al., 2013). From the late 1930s through the 1970s, the value of United States and Canadian commercial fisheries were relatively stable, with slight increases during the late 1940s and early 1950s due to increased yields of some species and increased demand following World War II. The value of harvested fish increased steadily from the 1970s through the early 1990s due to the recovery of native species, development of fisheries for exotic species, and worldwide increase in demand and prices for fishery products. Since the peak in 1992, value of commercial fishery yields have declined annually by 3.5% in the United States and 1.7% in Canada.

Lake Tanganyika, Africa's oldest and deepest (1470 m) lake, produces outstanding freshwater biological diversity and endemism (Cohen et al., 2016). It also provides up to 200,000 t of fish annually, comprising ~60% of regional animal protein consumed. Lake Malawi's fishes are a source of food for millions and provide a livelihood for thousands by encouraging tourism (Weyl et al., 2010). Lake Victoria (Tanzania side) accounts for over 60% of the total national inland fish production of Tanzania (Mgaya, 2012). However, declines in fish yields and shifts in species composition are serious concerns in the African Great Lakes of Tanganyika, Malawi (Nyasa/Niassa) and Victoria (Irvine et al., 2018). Despite management and regulatory structures, all the lakes remain as open-access fisheries, severely depressing yields, economic returns, and threatening biological diversity.

Shipping

Both lake vessels and ocean going vessels are used for international shipments in the Laurentian Great Lakes (Millerd, 2007). Lake vessels move grain and other agricultural products from Great Lakes ports to the lower St. Lawrence River and Gulf of St. Lawrence for trans-shipment. Both lake and ocean going ships move cargo into and out of the Great Lakes. Many ocean going ships will bring iron and steel products into the lakes and take out grain. Lake ships moving grain out of the lakes to the lower St. Lawrence River or Gulf of St. Lawrence will often take on a cargo of iron ore at a Gulf of St. Lawrence port for delivery to a Great Lakes steel mill.

Habitat Change

Eutrophication

Cultural eutrophication is thought to be the most widespread stressor of habitat for plants and animals in natural lakes (National Academy of Sciences, 1969; Hansen et al., 2010). This is particularly important because of its influence on health and food production associated with lakes in densely populated areas (Smith, 2003). About 30–40% of lakes worldwide are affected by unnaturally high nutrient concentrations leading to eutrophication (Uhlmann et al., 2011). Indications of eutrophication are high turbidity caused by algal blooms, dense macrophytes growths, food-web changes, mass development of toxin-producing cyanobacteria (i.e., blue-green algae), reduced species diversity, oxygen depletion, enrichment of reductive substances (e.g., toxic hydrogen sulfide), fish kills, and odors. Cultural eutrophication occurs when nutrients, primarily phosphorus and nitrogen, enter lakes from runoff or streams draining cattle feedlots, fields fertilized with chemicals or manure, sewage outfalls, or urban areas, at rates that exceed the decomposition rate in the lake (Kalff, 2002). The resulting oxygen deficit leads to kills of fish and other biota during

summer when stratification separates the hypolimnion from oxygen sources (photosynthesis and atmospheric oxygen) and in winter when ice and snow prevent photosynthesis and oxygen replenishment from the atmosphere.

Acidification

After eutrophication, acidification is the most important threat and stress factor for lakes (Uhlmann et al., 2011). Acid deposition has changed the natural water chemistry and the biological structure in 50,000–100,000 lakes and watercourses in Europe and North America. Acid rain is caused when burning coal produces sulfuric acid and nitric acid that are subsequently transported by wind to down-wind lakes (Haines, 1981). The vulnerability of lakes to acid rain is determined by their acid neutralizing capacity which is indexed by alkalinity. Areas underlain by limestone are less vulnerable to acidification even in the presence of acid rain (Hansen et al., 2010). Species richness in lakes is positively correlated to pH so acidification may negatively affect the number of species occupying lakes (Graham, 1993). Biota is also influenced by indirect consequences of acidification, such as increased release of potentially toxic metal ions (in particular aluminum, copper, cadmium, zinc, and lead) from soils and sediments (Uhlmann et al., 2011).

Shoreline Alteration

Alterations to shorelines of lakes through natural or anthropogenic forces may affect biological diversity in a variety of ways (Hansen et al., 2010). Human alterations to the riparian and littoral zones of lakes include aquatic and terrestrial vegetation removal, construction, dredging or filling on or near the shoreline, sand deposition, submerged woody debris removal, or seawall construction. Alterations such as these lead to accelerated rates of erosion and sedimentation, increased eutrophication, loss of aquatic plants and plant diversity, and invasion of nonnative plant species.

Invasive Species

Invasion of lakes by exotic species influences both physical and chemical environments in the littoral zone influencing abundance (Miranda and Pugh, 1997), survival (Miranda and Pugh, 1997), and growth (Olson et al., 1998) of native species.

Fish

Many lakes have experienced ecosystem changes due to invasive species (e.g., Smith et al., 2015). With their widespread distribution and likely more generalist habits, nonnative invasive fish may be contributing to the erosion of overall functional diversity of lacustrine fish assemblages (Kovalenko et al., 2019).

Invertebrates

Alien invertebrates are being discovered at increasing rates in large freshwater systems (Ricciardi, 2015). Multiple factors may be involved but human activities probably facilitate the majority of introductions. Rates of invasion by freshwater invertebrates in the Laurentian Great Lakes appear to be orders of magnitude greater now than before human influence (Ricciardi, 2006). Molecular evidence has shown that the current rate of invasion of North American lakes by European cladocerans is ~50,000 times greater than the prehistoric rate (Hebert and Cristescu, 2002).

Plants

Invasive plant species in lakes, and the associated large increase in biomass, strongly influences biological diversity in lakes (Hussner et al., 2009; Strayer, 2010). Invasive macrophytes can strongly modify local conditions in lakes, particularly water temperature, sediment chemistry, and nutrient cycling in the colonized area (Ribaudou et al., 2018).

Pollution

Contaminants of greatest concern in natural lakes, such as organochlorines, heavy metals, and mercury, are problematic because they are toxic, persistent, and often lipophilic, so they biomagnify and bioaccumulate in the biota (Kalff, 2002; Hansen et al., 2010). Contaminants have been linked to increased incidence of tumors in fish and possibly reproductive inhibition, but the most serious effects are felt in fish-eating birds and humans (Hansen et al., 2010). Therefore, birds and humans that eat contaminated fish are likely to suffer chronic effects related to toxicity of such substances.

Climate Change

Aquatic ecosystems are very vulnerable to climate change which influences the physical, chemical, and biological structure of lakes (Uhlmann et al., 2011). These influences include fluctuating water levels, increased water temperature, shorter ice-cover periods, invasion of nonindigenous animal and plant species from tropical and subtropical regions, and structural changes in catchment areas (e.g., soil erosion and land use). Most climate-change scenarios also show that the risk of eutrophication will increase due to a warmer climate.

Conservation and Management

Cultural Eutrophication

Methods for reducing nutrient levels that may cause cultural eutrophication include approaches that reduce (1) nutrient inputs (e.g., sewage treatment, wastewater diversion, wetland protection or construction, and buffer strips), (2) in-lake nutrient loads (inactivating phosphorus by adding aluminum sulfite, increasing phosphorus oxidation by adding lime, dredging nutrient-rich sediments, and harvesting aquatic macrophytes), or (3) oxygen-deficient water (pumping or aerating hypolimnetic water (Kalff, 2002; Hansen et al., 2010)).

Invasive Species

Many invasive species are invasive in a fraction of locales to which they are introduced, meaning that natural processes regulate their abundance at most sites (Bajer et al., 2019). It would be very valuable to understand what these limitations are and exploit them to design integrated pest management strategies based on natural processes.

Exotic plant species

Invasive aquatic plants may be removed or reduced by mechanical harvesting, application of herbicides, or stocking of plant-eating fish or invertebrates (Kalff, 2002). Target plants may be removed from all or selected areas of lakes using mechanical harvesters or herbicides, depending on objectives (e.g., beach esthetics, swimming) (Hansen et al., 2010). Mechanical harvesting has the advantage of removing plant biomass from the lake, while herbicides leave plant biomass in the lake for recycling of nutrients. Introducing plant-eating fish that feed on all plants, or plant-eating insects, that feed on single or a few target species of plants may be effective. However, introducing fishes and insects as biological agents for plant control may be risky because lakes are never closed systems, so introduced fish and insects, most of which are nonnative species, are likely to move to other lakes and rivers.

Invasive fish and invertebrates

Biological control is an approach to control populations of invasive species with other species. Means of biological control may include predators (Symondson et al., 2002), parasites or pathogens (Saunders et al., 2010), consumers (Malecki et al., 1993), or genetically modified organisms (Thresher et al., 2014). However, biological control of invasive fish and aquatic invertebrates remains rudimentary with only a few examples of success (Bajer et al., 2019). Control of invasives is still based primarily on physical removal by humans or predation by native species.

Acidification

Short-term treatment of acidification is possible through addition of lime (CaCO_3) directly to a lake (Clair and Hindar, 2005). Lime can be added to the entire lake surface but application of lime to specific areas of a lake may adequately increase pH enough to increase survival of organisms (Hasselrot and Hultberg, 1984). The only long-term solution to acidification is to reduce use of fossil fuels that produce acid constituents during combustion or to make combustion cleaner (Haines, 1981; Kalff, 2002).

Contaminants

The only apparent remedy is to eliminate sources, although aerial transport of contaminants makes elimination extremely difficult (Hansen et al., 2010).

Conclusions

Lakes world-wide are experiencing negative effects associated with increasing anthropogenic changes resulting from a growing human population and related development (Jeppesen et al., 2017). Consequently, many lakes are highly eutrophic and suffer from severe blooms of often toxic cyanobacteria and may become even more eutrophic in the future unless strong lake management actions are taken. Recent research has further shown that global warming and subsequent changes in water use will further

exacerbate eutrophication and invasive species in lakes. There is a growing need for expanded restoration of lakes and understanding and implementation of sustainable lake management.

Abstract

Springs are a unique resource from an ecological, economic, and cultural perspective. Springs harbor highly specialized and regionally restricted flora and fauna, often resulting in a unique freshwater biological diversity. Springs serve as evolutionary refugia, supporting concentrations of relict and endemic species that require habitat stability. Springs also provide a source of freshwater for personal human use and commercial sales. Major threats to springs include human draining and diversion of groundwater sources, pollution, alteration of habitat for associated flora and fauna, and invasive species. Moreover, restoration efforts are expensive and ecological responses to restoration are largely unknown. The safest management strategy is to refrain from potentially harmful land use within the vicinity of springs.

Introduction

In the early days of civilization, springs were regarded as sacred places (Williams, 1991). Springs provided refuges in arid landscapes and have been critical to the survival of indigenous peoples and also to European explorers and settlers (Scarsbrook et al., 2007). Springs were a reliable source of water for numerous human activities (e.g., irrigation, farming, mining, drinking) (Barquín and Scarsbrook, 2008).

Springs are unique from an ecological, economic, and cultural perspective (Rossi et al., 2015). Springs harbor highly specialized and regionally restricted flora and fauna, often resulting in unique freshwater biological diversity (Cantonati et al., 2012). Springs also serve as evolutionary refugia, supporting concentrations of relict and endemic species that require habitat stability (Davis et al., 2013).

Hydrologic and Geomorphologic Characteristics

Springs are formed when the water table intersects with the earth's surface, or groundwater rises to the surface through rock faults, fractures, or depressions (Death et al., 2004; Scarsbrook et al., 2007). Springs vary greatly in morphology and size, including minor seepages from bedrock faces, to resurgences in karst (e.g., the Bouillon de La Source resurgence, Albéric, 2004), up to very large vents discharging many thousands of liters per second (e.g., Homosassa Springs Group, Citrus County, Florida, USA). Thus, the main environmental drivers of spring ecosystems are the quantity and quality of groundwater inflow (Rossi et al., 2015). Natural variations in groundwater quantity and quality are controlled by a range of hydrogeological factors such as geology, topography, land cover, and recharge (Kresic and Stevanovic, 2009).

The distribution of springs is largely controlled by the volume and extent of groundwater recharge, the permeability of the geologic materials through which groundwater moves, geologic structure and faults, and topography (Cartwright and Johnson, 2018). A survey of 137 springs in the Crooked River subbasin of central Oregon revealed the hydrogeologic setting affects spring discharge type, temperature, and pH (Freed et al., 2019). Additional work in Iceland showed that spring type, temperature, and pH significantly subsequently influenced invertebrate community structure (Govoni et al., 2018).

Biological Characteristics

Springs provide stable habitats over years and even decades because their water comes from thermally buffered underground sources (Glazier, 2009; Kreiling et al., 2018). They are a transitional environment between cave conditions and surface stream

conditions. As such, springs provide benefits for a variety of aquatic and terrestrial organisms such as moisture, drinking water, food, minerals, shelter, thermal refuges, breeding sites, and travel corridors (Glazier, 2009; White, 2019).

Animal Communities

The relative constancy of the water temperature and flow rate of many springs affects the biotic composition in springs. Non emergent macroinvertebrates may have a competitive advantage over many insects in constant temperature springs because they can reproduce and maintain dense populations year-round, whereas insects must seasonally leave the water to breed as adults (Glazier, 2009). Non insect species are the most abundant macroinvertebrates in 78% of spring systems for which data are available. Macroinvertebrate abundance and diversity are influenced by consistent water flow, size of spring, substrate type and macrophyte density. The abundance and diversity of vertebrates may also be influenced by food availability; light conditions; substrate type; human influences; and water temperature, chemistry, and flow rate (Glazier, 2009).

Fish typically occur in large and persistent springs located on valley floors; few high-elevation springs are occupied by fish (Sada et al., 2001). These spring-dwelling fish are primarily threatened by establishment of nonnative fishes and macroinvertebrates and alteration of their habitat from water diversion for personal use and agriculture, excessive livestock grazing, and depletion of groundwater.

Commercial Uses

Springs have provided an obvious source of freshwater for human use (White, 2019). Villages and towns have grown up around springs because of the convenient supply of high-quality water. This has led to bottling and sale of spring water (LaMoreaux and Tanner, 2001). Some springs also attract thousands of tourists for sight-seeing (e.g., Silver Springs, Florida, USA) and bathing in warm, mineral waters.

Habitat Change

Springs throughout the world are not being properly managed and conserved and are disappearing rapidly, especially in arid regions (Glazier, 2009). Major threats to springs and their inhabitants include human draining and diversion of groundwater sources, pollution, alteration of habitat for associated species, and invasive species. Freed et al. (2019) found a high frequency of anthropogenic impacts on springs: 95% of diffuse-discharge springs and 79% of discrete-discharge springs they evaluated were disturbed by livestock grazing.

Pollution

Due to the rapid recharge and high velocities associated with karst aquifers, karst springs usually show high discharge dynamics. As a result, water quality often deteriorates very quickly following storm events due to the presence of contaminants such as pathogens, heavy metals, or pesticides (Schipperski, 2018).

Climate Change

As a result of climate change, hydrological cycles in many areas of the world have already been altered or soon will be (IPCC, 2014). Nevertheless, the groundwater supply to springs buffers surface and soil temperatures resulting in climate resilience of springs in some areas (Fernández-Pascual et al., 2015). Springs are potential hydrologic refugia from climate change (Cartwright and Johnson, 2018). Persistent wet or mesic microenvironments in springs that are relatively unassociated with regional climate could support climate resilience for natural communities (McLaughlin et al., 2017). Such hydrologic refugia may be particularly important in regions where droughts intensify (i.e., become more frequent or severe) as a result of climate change (Dai, 2012).

However, if water temperatures in springs do increase by several degrees there will likely be substantial impacts on biological diversity, causing regional extinctions of native, cold-stenothermal spring specialists (Jyväsjärvi et al., 2015). Even a slight (e.g., 1 °C) increase in water temperature may eliminate endemic spring species, thus altering bryophyte and macroinvertebrate assemblages of spring-fed streams.

Conservation and Management

Globally, springs suffer from groundwater depletion (Konikow and Kendy, 2005), contamination (e.g., nitrates, metals) (Laini et al., 2012), and anthropogenic disturbance (e.g., peatland drainage, livestock) (Aapala et al., 2013; Freed et al., 2019). Effective

conservation of spring-dependent ecosystems requires practical and cost-efficient means of identifying springs that are most likely to maintain their hydrologic and ecological functions within the landscape over time (Cartwright and Johnson, 2018). Because restoration efforts will be expensive and ecological responses to restoration are largely unknown, it may be necessary to emphasize springs that provide hydrologic refugia rather than those that may be influenced by climate change (Costelloe and Russell, 2014; Lehosmaa et al., 2017a,b). Restoration has been demonstrated to enhance the quality of habitats for species associated with springs; enhancement of biological diversity was detectable a few years post-restoration (Lehosmaa et al., 2017a,b).

Conclusions

Effective management of springs needs to consider the environmental and societal values associated with them, understand the threats to the sustainability of springs, and formulate strategies that provide a balance between potentially conflicting uses (Barquín and Scarsbrook, 2008).

Areas where spring ecosystems have been degraded by human alteration (Barquín and Scarsbrook, 2008; Ilmonen et al., 2013) will need restoration initiatives for long-term conservation of spring-dependent biological diversity. Without restoration measures that improve groundwater hydrology, the self-recovery potential of springs is very low. As little is currently known about the effectiveness of spring restoration in addressing the loss of biological diversity in springs, the safest management strategy is to refrain from potentially harmful land use within broad buffers around springs (e.g., > 40 m) (Selonen and Kotiaho, 2013; Lehosmaa et al., 2017a,b).

Abstract

Streams comprise only a small portion of Earth's terrestrial surface area yet harbor a significant amount of the world's biodiversity. These ecosystems also support many services to human society predisposing them to ecosystem alteration and leaving a very small percentage of streams in their natural state. Given their rarity and propensity for human disturbance, understanding stream structure and function, and how to conserve those properties, is extremely important. This chapter provides an overview of stream environments, their form and function, the organisms that inhabit them, and ecological concepts and paradigms. An overview of major types of commercial uses is provided, which correlates with anthropogenic stressors and the nature of ecosystem alteration. Finally, the chapter concludes with approaches and strategies for stream conservation and management.

All streams flow into the sea, yet the sea is never full. To the place the streams come from, there they return again.
Ecclesiastes 1:7

Introduction

Freshwater is rare on planet Earth. The majority of the world's water is found within oceans, whereas only 0.01% of surface water occurs within rivers, lakes and wetlands. Despite the rarity of freshwater environments, these ecosystems support a disproportionate amount of the world's biodiversity, boasting 126,000 species or at least 7% of Earth's described species ([Dudgeon et al., 2006](#); [Balain et al., 2008](#)).

Lotic systems are even rarer than other freshwater environments, but they play important roles in connecting aquatic and terrestrial environments. Streams constitute over 88 million km of ribbons connecting upland areas to oceans yet these environments comprise < 0.6% of the Earth's land surface ([Downing et al., 2012](#)). Natural freshwater lakes constitute over 4 million km² ([Downing et al., 2006](#)), which is over six times more area than rivers. However, the cumulative length of rivers is 21 times longer than the total shoreline perimeter of world lakes and 46 times longer than the world coastline ([Downing et al., 2012](#)). Hence, streams and rivers likely play significant roles in freshwater's interaction with the terrestrial landscape, including the transportation and modification of materials from terrestrial sources.

The longitudinal directionality of moving water, in concert with dynamic lateral connections to the adjacent terrestrial environment, craft the uniqueness of stream ecosystems and the organisms that inhabit them; however, these properties also render streams challenging systems to study. Additionally, moving water provides many valuable ecosystem services, which have been over-exploited by humans and led to many of the world's river basins existing in highly altered states. Given the rarity of these systems, future protection and conservation of river environments will be critical for provision of future ecosystem services and sustaining aquatic biodiversity.

What Is a Stream?

At a most basic level, a stream is a channel that carries water downhill from surrounding landscapes (Fig. 1). Streams range in size from small channels carrying occasional pulses of flow ($<0.03 \text{ m}^3 \text{ s}^{-1}$) during rainfall events to large systems, such as the Amazon River (Brazil), with discharges exceeding $200,000 \text{ m}^3 \text{ s}^{-1}$. Precipitation that falls on land evaporates, infiltrates the soil, or is shunted overland directly to streams (i.e., overland flow). Lateral flow refers to water that infiltrates the soil and flows downstream through the soil to a stream. Alternatively, water that infiltrates the soil may percolate to deeper soil horizons, where it enters groundwater (the water table).

Many streams carry surface water only a fraction of the time, and some only convey water during precipitation events. The latter type of stream is called an ephemeral channel, whereas streams carrying water at least a portion of year during the wet season are termed intermittent streams (Fig. 1B). Perennial streams, on the other hand, carry water year-round but can range dramatically in the duration of water conveyance. Some streams have continual wetted perimeters, whereas intermittent systems may have long periods of drying. Furthermore, sub-surface water flow may occur in streams where surface flow is not apparent. In karst terrain, “losing” reaches occur where streamflow decreases with downstream distance, only to re-emerge downstream.

Where groundwater intermixes with surface water is called the hyporheic zone. The hyporheic zone is the porous space beneath and alongside a stream bed, where shallow groundwater and surface water combine. Hyporheic flow is important for fish spawning and other biological processes. For example, salmonids build nests (“redds”) in upwelling and downwelling areas of stream gravel where eggs can incubate in a stable, groundwater-influenced thermal environment and metabolic wastes from developing eggs and larvae are removed by water fluxes into or from the sediment (Bjornn and Reiser, 1991; Groves and Chandler, 2005). For fall-spawning salmonids, the risk of freezing is lower in gravels with hyporheic exchange.

Physical Properties of Streams

Hydrology is the defining principle of stream environments, and accordingly, the amount of flow a stream carries has been used to classify different types of streams. To provide an inventory of streams in the landscape, however, it would be impossible to directly measure discharge ($\text{m}^3 \text{ s}^{-1}$) in all waterbodies. Horton (1945) and Strahler (1957) devised a classification for mapping streams based on identifying stream segments in maps; however, the granularity of such a system depends on the scale of each map. The smallest ephemeral streams are mapped as a 0-order streams, and where two ephemeral types join form a headwater stream—a 1st order stream, and the junction of two type 1 streams form a 2nd order stream, and so on (Fig. 2). However, each order is dependent upon the junction of two equally sized systems. For instance, the junction of a 1st and 2nd order system only results in a 2nd

Fig. 2 Strahler stream order diagram.

Fig. 3 Distribution of global rivers and their discharge. Data from Ouellet Dallaire et al. (2018).

order stream. The frequency of stream sizes in the landscape follows an exponential decay of abundance versus size, where headwaters are the most numerically abundant, comprising 52% of the total global stream length, and 12th order rivers are the rarest, comprising only 0.007% (Downing et al., 2012).

Each continent has a large river (Fig. 3) where size can be measured by total length or flow. Measuring the length of a river is challenging, and estimates remain uncertain. The Nile and Amazon Rivers are considered the two largest rivers. The Nile flows north across North Africa for 6650 km. Originating in the Andes Mountains on the South American continent, the Amazon River (~6400 km) is located mostly in Brazil and carries 7% of freshwater flow in the world ($209,000 \text{ m}^3 \text{ s}^{-1}$), more than any other river. Another major South American river is the Parana River (4880 km). The Chang Jiang (Yantze) River is 3rd longest in the world and the longest river on the Asian continent (6300 km). In North America, the fourth longest river is the Mississippi-Missouri River (5971 km). The Yanisei (5539 km) and Yellow Rivers (5454 km) are two major river systems on the Asian continent running through Mongolia and China, respectively. In Russia, the Ob River is a major river that runs 5463 km from the Altan Mountains to the Arctic Ocean. Australia is relatively dry continent. Its longest river is the Murray River (2508 km).

Streams are nested dendritic networks. Frissell et al. (1986) developed a hierarchical stream classification as a convenient way to represent the scale-dependence of stream habitats. At the coarsest level are watersheds or stream systems (10^3 m), representing the riverine landscape. The next levels are represented by stream segments (10^2 m), followed by stream reaches (10^1 m), meso-habitats (10^0 m , e.g., riffle, run, pool), and finally microhabitats (10^{-1} m).

Stream characteristics are determined by properties of the watersheds they drain and their hydrology reflects those characteristics (Hynes, 1975). Stream hydrology depends on the climate regime and properties of the watershed, such as topography and soil infiltration capacity. For instance, watersheds with low infiltration capacity (e.g., clay soils) shunt water quickly downhill and result in flashy, episodic hydrology, whereas watersheds with high rainfall and deep organic soils can store water and lead to high and stable baseflow conditions. A streams' hydrologic regime is quite specific, also referred to as its hydrologic signature (Fig. 4).

Streamflow is typically measured as discharge (e.g., $\text{m}^3 \text{ s}^{-1}$), which is a product of the stream's cross-section, its depth, and its velocity (Fig. 4). Flow regimes are partitioned into two main parts, baseflow (the sum of deep subsurface flow and delayed shallow subsurface flow) and event flow (elevated flows that occur following precipitation or snowmelt events). Flow regimes can be characterized by statistics including the magnitude, timing, duration, frequency, and rate-of-change of flow events. One controversial concept is that these statistics, when derived from unregulated rivers in pristine watersheds, comprises a stream's "natural flow regime" (Poff et al., 1997). A stream's flow regime influences material transport, channel and habitat structure, physiochemical characteristics, and the ecological communities that depend on these properties.

Fluvial geomorphology is largely governed by strong relationships among catchment area, discharge, stream width, slope, and sinuosity (Leopold, 1994; Frasson et al., 2019); hence, these relationships typically push streams toward a state of dynamic equilibrium, where changes in one geomorphic component result in changes to others (Leopold, 1994). Even so, a stream's hydrology interacts with the channel and surrounding floodplain in complex ways. In narrow valleys of mountainous terrain, streams are confined to a single channel (Fig. 5A), whereas in broad valleys streams are able to migrate laterally, even becoming braided

Fig. 4 Hydrologic regime for the Valley River, North Carolina, United States. Percentile statistics of discharge were calculated for each day of the year for US Geological Survey stream gage 03550000. Annual phases of the hydrograph are associated with life histories of many fish, especially spawning and recruitment.

Fig. 5 Stream channel variation with respect to valley topography and floodplain interaction. (A) steep confined channels have less floodplain interaction, whereas in (B) coastal low-gradient rivers, floodplains are more extensive. (C) The initiation of oxbow formation occurs in highly sinuous rivers where bends become side channels, and eventually (D) are completely cut off from routine flows. Diagrams provided by Tracy Saxby, Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/imagelibrary/).

Fig. 6 Longitudinal variation in geomorphology of the Pigeon River, North Carolina (United States) from steep mountainous terrain to broad valley with high interaction between the channel and floodplain. A clear progression from narrow and confined channels dominated by boulder and bedrock substrate to wider channels with extensive floodplain interactions and finer substrates of gravel and sand. with multiple channels (Fig. 5B). The longitudinal transition in geomorphology caused by confined valleys in mountainous terrain to unconstrained valleys can be observed in the Pigeon River Basin in western North Carolina, United States (Fig. 6).

When river flow is constrained within one channel (Fig. 7), the maximum discharge this channel can accommodate is termed the bankfull flow. The elevation of this flow within the channel can be determined based on morphometrics and physical marks on the stream bank (Fig. 7). Discharges exceeding the bankfull flow migrate into the floodplain. The frequency of bankfull flows (defined as inundating 1st floodplain) varies among streams and regions, although it typically re-occurs every 1.5–2 years. Bankfull flows are extremely important to maintaining channel dimensions and morphological units, such as the location of riffles and pools, their sequential pattern, and the location and extent of point and lateral bars (e.g., Fig. 1G, bars are deposits of stream material following high flow events) (Trush et al., 2000). Flows that inundate the floodplain may be constrained by a secondary channel. In this case, a secondary floodplain can exist (Fig. 7).

Stream channels and floodplains are dynamic (Fig. 8). Over time, stream channels evolve in response to physical disturbance regimes, such as changes in discharge (Fig. 8). The morphology of a stream depends on geomorphic properties of the surrounding valley, extreme flood events, and physical obstructions to flow, such as large woody debris (LWD). In steep tributaries, landslides caused by wildfire and/or high flows supply LWD and sediment, including large cobbles, to streams (Benda et al., 2004). At a local scale, LWD provides a focal point for deposition of fine sediments. Debris in channels creates roughness (i.e., resistance to flow), alters hydraulics, and tends to increase sinuosity and produce riffle-pool sequences. Rules describing the frequency of riffle and pools and relationships with sinuosity have been developed (Leopold, 1994). Typically, in broad valleys, channels increase in sinuosity over time and with distance downstream. They create slow-shallow habitats, such as oxbows and often become more braided in lower reaches (Fig. 5C). Over time, oxbows are eventually cut off from the main channel (Fig. 5D, Kramer and Wohl, 2017).

Streamflow is erosive and its ability to shape channel morphology depends on stream power (the magnitude of flow, along with gradient) and the particle size of substrates or roughness. Sand-dominated channels (e.g., Fig. 1E) will likely shift more than

Fig. 8 Dynamic changes in the channel and floodplain in the Little Colorado River, Arizona from 1936 to 2010. Channel and active floodplain shift dramatically year to year. Dramatic reductions in discharge from human uses result in narrower and more sinuous channels over time. Map redrawn using data from [Bloom \(2014\)](#).

boulder-dominated systems (e.g., Fig. 1A and C), as the latter tend to have confined channels. In broad valleys, stream channels may migrate laterally over time. Unless modified by human activities, overall sinuosity of streams within valleys may remain constant yet riffle, run and pool sequences may shift in location, although the relative length of these units also tend to stay constant over time for a given system. Additionally, sediment budgets typically remain in a constant state of dynamic equilibrium where inputs to any point equal outputs. At some locations, sediment inputs may exceed outputs leading to aggradation of the channel and increases in bed elevation, whereas when the opposite is true, degradation of the channel occurs.

Several classification systems have been developed to describe the diversity of stream morphologies (e.g., Rosgen, 1994). These rely on metrics such as channel slope (rise/run), sinuosity (channel length versus straight line distance), width:depth ratios, median particle size of streambed substrates, and entrenchment ratio. Entrenchment ratio is the width of the floodplain at $2 \times$ bank full height divided by bankfull width. Large ratios (>2) indicate high interaction between stream channels and their floodplains. Confluences where tributaries enter larger mainstems are important features of rivers that help to determine river network properties. These also provide special habitat qualities for aquatic life. Naiman et al. (2008) developed principles to relate stream network structure to physical properties of confluences, including a series of testable hypotheses.

Many organisms adapted to living in streams have narrow ranges of physiochemical tolerances. Streams draining iron-rich soils will likely have lower pH than those in limestone-rich areas. Temperature in small streams is largely driven by groundwater, which remains stable at roughly the average of above-ground annual temperature and has low concentrations of dissolved oxygen. Additionally, shade from riparian vegetation plays a larger role in maintaining lower temperatures in small streams. As streams become wider downstream, channels widen and receive more solar radiation leading to increased temperatures (Caissie, 2006). As a rule of thumb, stream widths less than twice the height of the riparian tree canopy are effectively shaded. Water has high thermal inertia and larger river channels have lower surface-to-volume ratios; hence, rivers maintain cool temperatures for extensive distances downstream. Dissolved oxygen is dependent on temperature but also aeration from turbulence and exchanges between the surface film and atmosphere. Importantly, dissolved oxygen, which is required by aquatic life, can be consumed by bacterial respiration of decaying algal blooms.

Stream Ecology

Major Concepts

Because streams are highly complex systems, several concepts emerged to describe stream ecosystem behavior and formulate hypotheses regarding their responses to disturbance. Stream ecosystem metabolism is driven by two sources of energy (carbon): allochthonous inputs (organic matter from trees) and autochthonous inputs (from within-stream primary production from algae or periphyton). The relative contribution of these inputs to streams plays a large role in organizing ecosystem structure and composition. In small headwater streams draining forested watersheds with deciduous vegetation, the primary source of energy is through coarse particulate organic material (CPOM) inputs. CPOM is colonized and chemically conditioned by bacterial and fungal microbial communities, and then it is partially consumed and processed into fine POM (FPOM) by leaf-shredding macroinvertebrates. FPOM is then consumed by multiple other types of invertebrates, such as collector-gatherers and collector-filterers. As streams increase in size and channels widen, riparian shading decreases and elevated light penetration increases autochthonous production. In some non-forested systems, autochthonous production can be high even within small streams. Periphyton communities provide food resources for other types of organisms, such as scrapers and collector-gatherers.

Longitudinally, river systems display gradual shifts in their relative balance of energy inputs from primary production (internal) versus allochthonous (external) carbon sources (Fig. 9). The River Continuum Concept (RCC) originated to describe the longitudinal progression of shifts in the energy budget of river systems (Vannote et al., 1980; Fig. 9). In headwater systems, allochthonous inputs dominate organic inputs, and the ratio of carbon sequestration through photosynthesis (P) to carbon respiration (R) is <1 . However, as streams widen and autochthonous production increases, P:R ratios become >1 . As stream depth increases, light penetration through the water column lowers and P:R ratios again return to <1 . Thus, P:R ratios assume a parabolic function where P:R ratios maximize at intermediate-sized river systems. As mentioned above, the source of carbon influences the functional composition of ecological communities along the river continuum. For instance, in headwaters the RCC postulates that leaf-shredding invertebrates and collectors would dominate macroinvertebrate communities whereas, as system size increases, the relative abundance of collector filterers and scrapers increase (Fig. 9).

Once streams deepen, collector gatherers and predators predominate invertebrate communities. Similarly, insectivorous fish predominate headwater stream communities and omnivorous and piscivorous fish increase as system size increases. Piscivorous fish predominate large river communities (Fig. 9).

Challenges and refinements to the RCC have been articulated over time. For example, blackwater rivers become more dependent on heterotrophic respiration from processing allochthonous organic material as rivers become wider near the coast (Meyer, 1990; Meyer and Edwards, 1990; Mallin et al., 2004). Photosynthesis becomes limited by dark tannins produced in wetlands and floodplains that restrict penetration of light. Despite the lower incidence of algal blooms, heterotrophic respiration can produce eutrophic conditions in blackwater rivers (Jager et al., 2011).

The role of floodplain wetlands illustrates another important paradigm in river ecology, the food-pulse concept (FPC) (Junk et al., 1989). This paradigm suggested that river system structure and function were largely dependent upon lateral hydrologic connectivity, specifically periodic disturbance of overbank floods. Floods mobilize sediments and organic material, shift channel

Fig. 9 The River Continuum Concept. Recreated from [Vannote et al. \(1980\)](#). Published with permission of NRC Research Press. Images of fauna and flora available from the Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/imagelibrary/).

morphology, maintain habitats, and shift organic material from the surrounding watershed to the stream ([Naiman et al., 2010](#)). Another concept, the Riverine Productivity Model ([Thorp and Delong, 1994](#)) suggests that riparian areas are important sources of organic matter inputs, specifically large autochthonous material such as large wood, which creates discrete areas of higher system productivity (e.g., fish abundance) as opposed to longitudinal progression in ecosystem balances between autochthonous and allochthonous resources. Geographic provinces vary in geology, which exerts controls on valley topography and geomorphic process in streams. The Process Domains Concept (PDC), postulates that geological landscapes or patches impose stronger controls than longitudinal processes on stream geomorphology and physiochemical characteristics, which then organize ecological communities ([Montgomery, 1999](#)). More recent frameworks emerged that built upon, or even cross-cut, these original paradigms. For instance, the Riverine Ecosystem Synthesis ([Thorp et al., 2006](#)) attempts to unify the longitudinal and lateral connectivity of riverine processes and networks with the broad discontinuous patterns of important landscape features.

Organisms Adapted to Living in Streams and Ecological Communities

Lotic systems induce very different selection pressures on organisms than their lentic counterparts. Among plants, special adaptations include hydrochory (life histories that depend on dispersal of seeds, fruits, and spores by water). Riparian woody species that colonize along rivers are pioneer species adapted to withstand and recover from floods. These include adaptations to counteract anoxic conditions during floods, flexible stems, floating seeds, and the ability to propagate from drifting stems ([Naiman and Decamps, 1997](#)).

Among aquatic animals, flowing water imposes energetic demands on organisms exerting effort to remain fixed or move upstream within the water column to feed or carry out their life history needs ([Fig. 10](#)). Body morphologies are evidence of

Fig. 10 Animals adapted for life in stream environments. (A) *Rhithrogena brunneotincta*, a species of flathead mayfly of the family Heptageniidae, (B) a caddisfly larvae in the genus *Cheumatopsyche* (family Hydropsychidae), (C) female *Acerpenna pygmaea*, a mayfly in the family Baetidae, (D) stripetail darter, *Etheostoma kennicotti*, (E) Tennessee dace, *Phoxinus tennesseensis*, (F) Blueside darter, *Etheostoma jessiae*, (G) largescale stoneroller, *Campostoma oligocephalus*, and (H) cartilaginous ridge on lower lip of *Campostoma* for scraping algae. adaptation strategies to minimize drag in rapidly moving fluid environments. For instance, larval stages of Heptageniid mayflies have evolved very wide, dorsoventrally flattened bodies to minimize body exposure to swift currents and cling to substrates to feed on periphyton (Fig. 10A). As another example, pelvic fins of freshwater gobies in Hawaii (*Lentipes concolor* and *Sicyopterus japonicus*) evolved into suction disks to scale waterfalls in order to migrate. Other body morphologies show adaptations to feeding or reproduction strategies in streams. Fish of the genera *Camptostoma*, have a rigid cartilaginous ridge on their lower lip to scrape algae from substrate (Fig. 10G and H).

Animals also have very interesting behaviors adapted to living in flowing environments. Nearly all river biota perform an upstream migration during one life stage to counteract downstream passive drift during another life stage (usually an early life stage). We refer to this as a “conveyor-belt” life history. Migration distances vary, but typically involve movements to find habitats suitable for different purposes, such as reproduction, feeding/growth, and resting/cover. For instances, Tennessee dace (*Phoxinus tennesseensis*) are small minnows inhabiting 1st and 2nd order forested streams in the Tennessee River Basin, United States (Fig. 10E). During high flows in spring, they migrate into small headwaters to spawn. Long-distance migrations are classified as potamodromous (within river), amphidromous (to an estuary to feed or growth during short periods, followed by upstream migration), anadromous (marine to upstream spawning habitat), and catadromous (rear in freshwater and migrate to the marine environment to spawn) (Lucas and Baras, 2001). Salmon exemplify the anadromous life history, eels follow a catadromous life history, Hawaiian gobies (mentioned previously) follow the amphidromous life history, and different species of sturgeon (Acipenseridae) follow each of these spatial patterns.

At a local scale, biota have adaptations to flowing waters. For example, caddisfly larvae in the family Hydropsychidae, also known as “net-spinning” caddisflies (Fig. 10B), construct nets of silk for refugia and feeding by capturing particles of FPOM in transport, also called seston. Many fish species have adapted a variety of strategies for protecting eggs by depositing, burying, or hiding them within crevices of substrates (lithophils), depositing them on plants (phytolithophils), or broad casting them where they may drift downstream for up to hundreds of kilometers (Balon, 1975). Salmonids (trout and salmon) are an example of brood-hiding fishes where females will use their tails and bodies to prepare a nest called a “redd” by cleaning fine sediments from gravel and

Fig. 11 *Nocomis* chub mounds are elaborate nesting sites that provide spawning habitat for multiple other fish species. cobble substrates. As females undulate their bodies and release the roe, a male will come alongside the female and fertilize eggs with milt, and the eggs settle within the interstitial spaces of substrates. Males of the genera *Nocomis*, known as the mound building chubs, develop elaborate mounds of gravel by carrying substrate particles in their mouth (Fig. 11). Eggs are fertilized and deposited within the mound following construction. *Nocomis* nests also provide important spawning habitat for other fish species, called nest associates (Fig. 11, Peoples and Frimpong, 2013, 2016; Frimpong, 2018). *Nocomis* mounds provide contiguous patches of highly porous gravel substrates, which would otherwise be unavailable in streams where they occur (Pendleton et al., 2012). It is believed that the relationship between mound-building chubs and nest associates is mutually beneficial, as *Nocomis* mounds are safeguarded by these other species (Fig. 11, Peoples and Frimpong, 2013; Frimpong, 2018).

Stream flow acts as a “master variable” (Power et al., 1995), controlling the geomorphology, physiochemistry, and habitat structure that sustain the ecological integrity of river systems (Poff et al., 1997). The specific natural flow regime signature of rivers (Poff et al., 1997) acts a template or filter of selective pressures, in which many organisms have adapted, and hence, require for carrying out their life history requirements (Fig. 4, Poff and Ward, 1989; Bunn and Arthington, 2002). For instance, discharge and water temperature must reach optimal ranges to induce spawning for many fish species, such as Chinese sturgeon (*Acipenser sinensis*) in the Yangtze River (Deguo et al., 2007), whereas the timing, duration, and magnitude of seasonal floods serve as cues for spawning for many species (Bunn and Arthington, 2002), but also provide cues for hatching and downstream drift of others (Næsjø et al., 1995). The frequency and intensity of flooding is important for scouring floodplains and reducing competition for non-native vegetation in favor of native riparian vegetation. For example, Virginia spirea (*Spiraea virginiana*), a rare and threatened perennial plant species of the Southern Appalachians of the United States, has fibrous clonal roots that can fragment and establish elsewhere. This species relies on floods of sufficient magnitude and frequency to scour and maintain floodplains while not dislodging the species.

General hypotheses linking hydrologic regimes and fish life histories have been useful for understanding the role of hydrology in organizing community structure. Fish life histories represent a tri-continuum of tradeoffs among three opposing endpoints, representing alternative strategies in life span, body size, fecundity, parental care, and number of spawning bouts within a season (Winemiller and Rose, 1992). On one endpoint, equilibrium species represent a K-strategy characterized by small-bodied fish with average life-span, low fecundity, only one spawning bout a year, and high parental care. Similar to other K-strategists, these species prefer stable conditions, like low-variant stream flows. Examples of stream-dwelling equilibrium fish species include small algal-grazing minnows, such as central stoneroller (*Camptostoma anomalum*). The other two endpoints split the r-strategy into two groups, periodic and opportunistic species. Periodic species, such as sturgeon, are long-lived, attain large sizes, have high fecundity, spawn no more than once per season, and invest very little in their progeny. These tend to be “capital-breeding” species that accumulate energy over multiple years before they invest in reproduction, for example, by making a long spawning migration (Jager et al., 2008). Periodic species prefer seasonally variant but predictable flows that provide suitable conditions for spawning every several years. Opportunistic species are short-lived, small sized, have average fecundity, and may have multiple spawning bouts per season. Opportunists, such as minnows within the genus *Notropis*, prefer highly variable flows and, at times, intermittent systems, as they can quickly colonize and re-establish populations once flows return.

Stream community structure and composition is dependent upon stream size, the primary productivity of the region, position within the stream network (e.g., near tributaries), and geographic radiation of species. The RCC postulates that the diversity of food resources (i.e., sources of energy) is maximized at intermediate stream sizes. Functional group diversity then should also maximize at intermediate-sized systems, and therefore, the RCC suggests that these medium-sized systems should harbor the highest diversity levels. However, fish species richness increases as a log-log relationship with river discharge where diversity is maximized at the largest system size (Xenopoulos and Lodge, 2006), as opposed to displaying a parabolic relationship with discharge.

Many complex relationships exist among species, such as competition, predation, parasitology, and symbiosis, are apparent in stream communities, as in other ecosystems. As mentioned earlier, an example of symbiosis is the utilization of *Nocomis* species spawning mounds by several fish species, whose recruitment may depend on the presence of *Nocomis*. Freshwater mussel life histories involve several phases and require a fish host. Male mussels release sperm, which is filtered by females to fertilize eggs. Larval mussels, called glochidia, are aggregated on a soft tissue, called a “lure”, which represent small fish or invertebrates. Fish bite the lures and parasitic glochidia attach to their gills and grow until attaining a sufficient size to release to the sediment, where they partially bury themselves.

Commercial Importance and Ecosystem Services

For thousands of years, humans have settled along rivers due to their provision of services (Böck et al., 2018). In North America, Indian tribes relied on rivers for fish food subsidies or areas that funneled large mammal crossings for hunting (Park et al., 2016), and as such, rivers were considered sacred places, providing sustenance for communities and a connective tissue linking distance lands supporting long-distance navigation and transport of commodities for trade (Marchand, 2013). Indeed, in the Corps of Discovery Expedition, commissioned by United States President Thomas Jefferson in 1804, rivers were envisioned as important routes for establishing new territory, connecting large land assets, and enabling trade. Rivers have served as sources of water for irrigation, boundaries of tribal lands, and eventually countries and states, whereas the junction of great rivers served as distinct landmarks for social meetings and eventual cities where major tributaries joined.

In modern day society, rivers still serve many of the same important purposes as they have for previous millennia, although many of these demands have become increasingly conflicted over limited resources. Rivers are a conundrum of jurisdictions and

shared resources. For instance, they provide sources of replenished drinking water while also serving as recipients of human waste. Because lotic systems dilute and metabolize contaminants, they have provided a convenient resource for handling treated and untreated waste from communities and transporting those materials downstream (Hardin, 1968). In under-developed countries, rivers still provide important food subsidies for local communities. For instance, indigenous peoples of the Amazon River basin and multiple nationalities of the Mekong River rely on these systems for protein. In developed countries, however, very few rivers still provide food subsidies at scales similar to resource provisions available to historical communities. To avoid overharvest, rivers in developed nations primarily consist of recreational fisheries. Rivers continue to be used for navigation, such as freight shipping, and the construction of locks and dams have expanded the transportation potential of rivers. Currently, over 275 million hectares are irrigated worldwide, accounting for 40% of total crop production (FAO, 2016a). The vast majority of the source water for irrigation comes from rivers. Rivers also provide an important source of water for thermoelectric facilities. Coal-fired power plants and nuclear power plants account for 40% and 11%, respectively (WEC, 2019), of electricity production, and these technologies typically rely on water for steam generation or cooling generators.

Rivers are also predisposed to human utilization because they provide a continual source of potential energy. Elevational gradients that precipitate downhill movement of water have been harnessed for conducting work for thousands of years. Small dams and diversions were developed to route water for powering or increase the elevation (i.e., potential energy) of water. Water-wheels and water-powered grist mills were in operation as early as the 4th century BC in the Persian Empire (Reynolds, 2002; Selin, 2013), but became commonplace worldwide by at least by the 10th century (Hill, 2013). Small hydropower dams were constructed to generate electricity as early as the late 19th century (DOE, 2008). Although a small fraction of historical grist mills are still in operation, hydropower continues to grow and currently supplies 16% of the world's electricity and over 70% of all renewable energy resources (WEC, 2019).

Anthropogenic Threats

As with much of the world's natural resources, human reliance on rivers has increasingly converted from a model of resource use to abuse. Earth's growing human populations and increasing demands for goods and services have left very few rivers in their natural state. Over half of Earth's accessible freshwater runoff is used by humans (Vitousek et al., 1997) and only one third of the world's great rivers flow freely to oceans without impoundment (Grill et al., 2019). Large rivers arguably bear most of burden of human demands—over 50% of large rivers ($\geq 1000 \text{ m}^3 \text{ s}^{-1}$) are significantly regulated by dams for water supply, flood control, navigation, and hydropower (Lehner et al., 2011). However, in the United States, 80% of streams, primarily comprised of small systems, show some sign of hydrologic alteration (McManamay et al., 2017). In the last century, global withdrawals have increased almost 7 times, a rate that is $1.7 \times$ that of population growth (FAO, 2016b). Forty-nine countries are currently classified as water stressed (FAO, 2016b), and this has been shown to increase the risk of armed regional conflicts (Mach et al., 2019).

One-third of all vertebrate species are confined to freshwater (Dudgeon et al., 2006). Given the rarity of these systems and their disproportionate role in sustaining biodiversity, the implications of human alterations to stream environments have been devastating to global biodiversity loss, the majority of which has occurred within the last few decades. From 1970 to 2014, freshwater populations have declined, on average, by 83% or by 4% per year (WWF, 2018). Currently, almost one in three freshwater species is threatened with extinction world-wide (Collen et al., 2014). For lotic environments, 34% of species are threatened (Collen et al., 2014), representing a higher proportion of species than in lakes or marshes. The likelihood of a species being in jeopardy is, in part, due to their life histories and requirements for habitats with greater propensity of human use and alteration. For instance, darters are typical of endemic freshwater species (Fig. 10D and F), which tend to have highly localized distributions in rugged landscapes (e.g., the Southern Appalachian Mountains) with small, relatively isolated watersheds. Other types of freshwater species that tend to be at risk include cave-dwelling fishes, gastropods, and mussels and spring-dwelling species. Similarly, the desert pupfish is now rare in arid environments where it was once common in the Southwestern United States and Mexico. Migratory species tend to be at higher risk because they require multiple habitats and safe corridors to pass between them. Although salmon are highly valued species, many runs of salmon are at risk in Western North America. Large-bodied species that are slow to mature, like sturgeons also tend to be at risk.

Dudgeon et al. (2006) lists five major categories of threats to freshwater biodiversity: overexploitation, water pollution, habitat modification, invasive species, and flow modification. Global-scale alterations, such as climate change, may influence multiple risks simultaneously and create compounding stressors, such as loss of thermal refugia (Isaak et al., 2012; Torgersen et al., 2001). Generally, overexploitation of river stocks is more common in underdeveloped countries where communities are highly reliant on freshwater fish as a source of protein. The United States and Canada, however, provided a globally important source of Atlantic sturgeon (*Acipenser oxyrinchus oxyrinchus*) meat and caviar during 1880–1900, and over-fishing is considered one of the major reasons for decline of the taxa (van Eenennaam et al., 2004). With the loss of other sources of caviar, paddlefish from North America became a premier source of caviar in 1980 and illegal harvests became rampant leading to declines in the species (Saffron, 2004).

Water pollution can be generally described as any change to the natural physiochemistry of waters. This includes pollutants, but also human-induced alterations to water temperature, conductivity, salinity, pH, and dissolved oxygen that may be outside or, in the least, constitute a stress to the physiological tolerance of aquatic organisms. Despite the improvement of water quality due technological advances in pollutant removal and imposed regulations, at least 80% of global human wastewater remains untreated (UN, 2017). Major classes of pollutants found in waters include wastewater, stormwater and non-point source pollution, nutrients,

sediments, metals, surfactants, organic pollutants, pharmaceuticals, endocrine disruptors, pesticides, petroleum hydrocarbons and polycyclic aromatic hydrocarbons (PAHs), ionic liquids, and nanomaterials (Pal et al., 2010; Choudri et al., 2017). Many of these compounds are persistent in stream environments and resistant to degradation via microbial community metabolism (Pal et al., 2010). Excess nutrients from agriculture runoff, sewage, and industrial wastewater have contributed to the increasing prevalence of cyanobacterial blooms, many of which produce toxins as a byproduct harmful to humans and wildlife (Cheung et al., 2013). Mercury is a globally abundant contaminant, acting as a neurotoxin to humans and wildlife. Humans have increased the atmospheric concentration of mercury 450% above natural levels, and land-use practices and point-source pollution are estimated to contribute 580 tons of mercury to aquatic environments annually (UN, 2019). Over 80% of fish samples and over 80% human hair samples across the world exceed US Environmental Protection Agency's reference dose values (BRI & IPEN, 2014).

Habitat and flow modifications in lotic environments occurs through direct (e.g., channelization) and indirect means (e.g., land use). Land transformation in upstream watersheds or in riparian areas alters hydrology, alters sediment regimes, and reduces shading from vegetation and organic matter contribution to streams. Deforestation reduces the forest canopy's interception of rainfall, reduces soil organic material, and increases soil erosion, all of which increases episodic runoff, sediment contributions to streams, and elevated air and water temperatures. Likewise, cultivation of the land surface for agricultural production increases sediment and nutrient contributions to streams, increasing siltation of streambeds and algal production. Conversion of permeable land cover to impervious surfaces in urban environments reduces the infiltration of precipitation, leading to increased stormflow magnitudes, loss of sediment and organic matter contributions, and elevated temperatures. Streams have been channelized and their banks armored to control lateral migration and prevent risk of human infrastructure failure. Over 160,000 km of levees have been constructed in the United States to constrain river flows and channel migration; however, the vast majority of these are outdated and need repair (AIR, 2014). In England, 65% of floodplains have been extensively altered due to agriculture leading to a virtual loss in fen, marsh, swamp and bog wetland habitats (Entwistle et al., 2019). Diversions for irrigation and water supply have left rivers with dramatically reduced flows. For instance, streamflow within the Colorado River at Hoover Dam, Arizona (United States) is reduced by at least 50% from pre-dam development periods and the river runs completely dry prior to entering the Pacific Ocean.

Arguably, dams induce the most dramatic alterations to river habitats (Petts, 1984), notably the conversion of lotic systems to lentic habitat. Many river organisms' life histories require flowing water; hence, these organisms are maladapted for life in reservoirs. Water storage in reservoirs alters downstream hydrologic regimes, traps sediment, and induces major shifts in temperature, dissolved oxygen, and other water quality parameters, leading to species declines. Depending on the size of the reservoir, these shifts in hydrology, sediment supplies, and water quality may be apparent for hundreds to thousands of kilometers downstream (Ward and Stanford, 1983; Schmidt and Wilcock, 2008). There are an estimated 16.7 million reservoirs worldwide which have increased the Earth's terrestrial surface water by 7.3% (Lehner et al., 2011). Of these reservoirs, approximately 57,000 are created by large dams (> 15 m height) (International Rivers, 2019). As of 2015, 3700 large dams at least 1 MW in size were either planned or under construction globally, and these facilities, once constructed, would increase global hydroelectricity capacity by 73% (Zarfl et al., 2015). Some of the world's great free-flowing rivers, such as the Amazon (Brazil), Congo (Africa), and Mekong (Asia) are at the highest risk of widespread dam development.

Invasive species are introduced through aquaculture, sport fishing, wild stock augmentation, aquarium trade, and biological control. Approximately 10,000 non-native species occur in waterways of the United States (USFWS, 2019). After establishment, invasive species often create new functional roles in aquatic ecosystems and communities, either directly, that is, competition/predation, or indirectly by changing habitat conditions (e.g., water quality) (Gallardo et al., 2016). In a global meta-analysis, effects of invasive species introductions resulted in predominately negative impacts on aquatic ecosystems, consistently reducing the abundance of native fish, benthic invertebrates, zooplankton, macrophytes, and phytoplankton; however, reductions in native species diversity were not consistently documented (Gallardo et al., 2016). Invaders tended to coincide with systems having higher organic matter and higher nutrient content, suggesting these habitats were typically altered by new functional roles by these species (Gallardo et al., 2016). Major alterations to habitat and flow regimes of rivers, such as impoundment and river regulation, create stable environments or new niche spaces that favor the establishment of invasive species.

Conservation and Management

Ecosystem conservation and management, particularly for streams, can be partitioned into two major strategies: (1) protection and/or prevention, or (2) mitigation and restoration. Regulations, legislative mandates, and policies may have application to one or both of these strategies and these vary widely among countries. We provide a brief overview of United-States (US)-centric federal protections of rivers, their protective provisions, and their lack thereof. In the United States, federal protections of river ecosystems are governed by the Clean Water Act (CWA), the Clean Air Act, the Endangered Species Act (ESA), the National Environmental Policy Act (NEPA), National Wild and Scenic River designations, and, for rivers influenced by non-federal hydropower facilities, the Federal Energy Regulatory Commission (FERC) licensing stipulations.

The US Federal Clean Water Act (CWA) commands the US Environmental Protection Agency (EPA) to pursue two policy goals. First, to restore and maintain the nation's waters; and second, to preserve each state's primary responsibility and right to prevent, reduce, and eliminate pollution. CWA was passed in 1972 (33 U.S.C. §1251 et seq.) and amended in 1975 (P.L. 95-217). Section 401 requires discharge permits for wastewater and pollutants, oil-spill prevention and response plans, and plans to clean up waters

that fail to meet state water-quality standards. The CWA has been very successful at improving water quality conditions in many industrialized and contaminated waterways in the US; however, here are several concerns about the ability of CWA to protect US rivers. First, a recent proposed ruling redefines “waters of the United States” or (WOTUS) to exclude headwaters, and therefore excludes the majority of reaches from protections (Federal Register 84 FR 4154, February 14, 2019). Secondly, agricultural and other “non-point” sources of pollutants are excluded from the law, and this has contributed to the serious degradation of water quality that manifests as algal blooms in lakes, reservoirs, and downstream estuaries.

Another piece of US legislation that has benefited rivers and streams in the United States is the Clean Air Act of 1963 (42 U.S.C. § 7401). This Act limited emissions of sulfate and nitrous oxides, and by doing so, it reversed freshwater acidification that affected rivers and streams. Sulfate concentrations declined from 30 million tons per year in 1970 to <5 in 2018, with similar reductions in nitrous oxides (Sullivan et al., 2018). Improved acid-base chemistry has been documented in hundreds of montane lakes throughout the northeastern United States (Strock et al., 2014). Reductions in mercury and lead deposition have also improved the safety of consuming freshwater fishes (Sullivan et al., 2018).

In the United States, the Endangered Species Act (ESA, 16 U.S.C. §1531 et seq.) was passed in 1973 and aimed to conserve threatened and endangered plants and animals and their habitats. The ESA is administered by the US Fish and Wildlife Service (USFWS) for freshwaters and by National Oceanic and Atmospheric Administration (NOAA) Fisheries for marine and anadromous fishes. The law requires federal agencies, in consultation with USFWS and/or NOAA to ensure actions they authorize, fund, or carry out are not likely to jeopardize the existence of listed species or result in harm to their environment. One of the first cases litigated (unsuccessfully) under the act was to prevent the building of Tellico Dam in East Tennessee, United States, to protect the snail darter (*Percina tanasi*), a species identified by taxonomist, David Etnier (Gilmer, 2013). For anadromous fishes in the western United States, the goal is to promote recovery of spawning “runs” to historical numbers and to preserve spatial diversity in salmon spawning habitat. Many fish and mussel species now listed under ESA are supported by artificial propagation in hatcheries because in-stream habitat is no longer adequate for reproduction. The goal of restoration efforts is to improve in-stream breeding habitat to eliminate the need for hatcheries.

The afore-mentioned regulations and policies are the primary driver behind a > 1 billion USD river restoration business within the United States (Bernhardt et al., 2005). Restoration approaches vary considerably in scale and type of applications (e.g., Fig. 12); however, the most cited objectives of projects were to improve water quality, manage riparian areas, enhance in-stream habitat,

Fig. 12 Examples of river restoration specifically bank stabilization and habitat enhancement. Diagrams depicting (A) a cross vein to direct erosive flows away from outside meander of a channel, (B) a cross vein weir to direct flows to the center of the channel and prevent erosion, while also creating deeper run habitat, (C and D) photographs of a type of cross vein, termed a “J Hook”, installed in the Pigeon River, North Carolina. Diagrams A and B provided by Tracy Saxby, Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/imagelibrary/). Photographs taken by Ryan McManamay.

improve fish passage, or stabilize stream banks to prevent erosion (Fig. 12) (Bernhardt et al., 2005). Unfortunately, rates of success for restoration projects are quite low, and most projects are implemented without adequate monitoring (Palmer et al., 2010). Applications either fail to restore processes that sustain river ecosystem integrity (Roni et al., 2008) or there is a mismatch between the scale at which restoration project is implemented and the scale at which disturbances are operating (Bernhardt and Palmer, 2011).

Decades of growing expenditures to restore degraded rivers have emphasized a need for preventative measures and protection of rivers from human disturbance. Protection of land assets, especially floodplains and riparian areas, varies globally (Fig. 13A). For example, over 53% of lands within Venezuela, Slovenia, and Monaco are protected. Although Hong Kong is among the most densely populated countries in the world, over 40% of its lands are protected. In comparison, only 14% of US lands are protected; however, land protection does not complement river needs. Whereas the majority of species at risk occur in the Southeast United States, more watersheds are protected from development in the Western United States, causing a mismatch between protections and risk (Jenkins et al., 2015).

Fig. 13 (A) Global distribution of protected lands and (B) distribution of rivers protected under the National Wild and Scenic River System (NWSRS). Global protected lands provided by the IUCN World Database on Protected Areas. Data for NWSRS provided by the National Park Service.

Of course, land protection may not adequately protect rivers unless conservation provisions extend throughout the entire river corridor. The National Wild and Scenic Rivers System (NWSRS) was created explicitly for that purpose and is the highest level of protection provisioned to a river (Fig. 13B). The NWSRS was established in 1968 (Public Law 90-542; 16 U.S.C. 1271 et seq.) to preserve rivers with outstanding natural, cultural, and recreational values in a free-flowing condition for the enjoyment of present and future generations. The purpose of the act was to complement policies favoring dam and other development with preservation of other selected rivers sections to protect the water quality and fulfill other vital national conservation purposes. While the NWSRS ensures rivers under its jurisdiction will retain their legacy as free-flowing, < 0.25% of rivers in the United States are protected under the NWSRS. More research is needed to understand the best provision of protection for rivers while also balancing the needs of human society.

Abstract

Ecosystems associated with rivers are intricately connected to their entire watershed. The river ecosystem includes the channel of active water flow, floodplain, and riparian and hyporheic zones. This ecosystem is shaped by interactions among the natural flow of water, sediments within the river and entering the river, and large wood regimes within the riparian zone. River integrity describes the ability of a river ecosystem to adjust to changes in these elements and through these adjustments maintain the habitat, disturbance regime, and connectivity necessary to sustain native biotic communities. Riverine food webs conceptualize the coupling between the physical environment and biotic communities and can be used to examine recovery from disturbance, variation in the structure of communities, and sources of energy that fuel metabolism within the ecosystem.

Introduction

Although rivers are sometimes regarded as relatively simple systems for downstream conveyance of water and other materials, rivers are most appropriately conceptualized as ecosystems that are intricately connected to the greater surrounding landscape and, eventually, the oceans. In this paper, we briefly discuss some of the principal physical and biological aspects of river ecosystems.

Basic Characteristics

Physical

A river corridor consists of some combination of the active channel(s), floodplain, riparian zone, and hyporheic zone (the area beneath the river bed and floodplain, in which surface and ground waters mix). Erosional and depositional forms created by river processes typically delineate the active channel, which in most regions is defined by that part of the river corridor that does not support mature woody vegetation (Osterkamp and Hedman, 1977; Arnaud et al., 2015). The upper elevation limit at which water is contained within a channel distinguishes the active channel from adjacent floodplain areas. A river corridor can have more than one active channel where multiple, subparallel channels branch and rejoin downstream, or where secondary channels are present. Secondary channels contain flowing water only during higher discharges (Fig. 1).

A floodplain is a relatively flat sedimentary surface adjacent to the active channel that is built by contemporary river processes and that is frequently inundated during floods (Nanson and Croke, 1992; Dunne and Aalto, 2013). The lateral extent of a floodplain can also be defined in a regulatory context based on the area inundated by a flow with a specific return interval: this

Fig. 1 Aerial view of a portion of the Kobuk River in interior Alaska, USA with multiple active channels. Flow direction is from upper right to lower left.

leads to definition of a 100-year floodplain, for example. River scientists typically describe a floodplain as the surface that is flooded on average at least once every 2 years. Rivers with highly variable flow, however, such as those in arid lands, can have flat surfaces adjacent to the channel which are composed of contemporary river sediments that are flooded only every few decades (Williams, 1978).

The riparian zone is the interface between terrestrial and aquatic systems (Naiman et al., 2005). The US Army Corps of Engineers, which oversees regulatory delineations for freshwaters in the United States, has defined riparian areas as “lands adjacent to streams . . . transitional between terrestrial and aquatic ecosystems, through which surface and subsurface hydrology connects riverine, lacustrine, estuarine, and marine waters with their adjacent wetlands, non-wetland waters, or uplands” (USACE, 2012). The lateral extent of the riparian zone can also be defined as the surface extent of frequent flooding and the subsurface extent of mixing of river, hyporheic, and ground waters (Wohl, 2014a), creating substantial overlap with the definition of floodplains. Riparian zones can occur in portions of the river network that do not have floodplains, such as steep sided, narrow canyons.

The hyporheic zone is the area in stream sediments where surface water and groundwater mix. This zone can extend several meters below large alluvial rivers (alluvial channels are those formed in unconsolidated sediments deposited by the river) and as far as 2 km laterally from the active channel in river corridors with broad floodplains underlain by gravel (Stanford and Ward, 1988; Gooseff, 2010).

Water and sediment inputs are the primary drivers of physical form and process in all rivers. In forested river corridors, large wood (typically defined as >10 cm diameter and 1 m length) historically formed an equally important component (Fig. 2). However, centuries of large wood removal in many river networks have reduced the influence of wood on channels and floodplains (Montgomery et al., 2003; Wohl, 2014b).

Water flowing downstream converts potential energy to kinetic energy, which is expended in overcoming frictional resistance, transporting sediment, and eroding the channel boundaries. The amount of stream energy available at any point in space and time reflects the volume of water flowing downstream and the valley and channel geometry, which influence downstream gradient and frictional resistance. The work exerted by the stream flow reflects the balance between available energy and the erosional resistance of the channel substrate. Substrate erosional resistance results from substrate composition and additional resistance created by living aquatic and riparian vegetation and dead vegetation in the form of instream and floodplain wood.

Understanding energy expenditure of stream flow is important in the context of river corridor stability. If stream flow energy increases substantially because of increasing discharge, such as during a flood, available energy can exceed the erosional resistance of the channel boundaries, resulting in erosion of the bed or channel widening. Conversely, if stream flow energy is insufficient to perform the work of transporting sediment supplied to the river corridor, sediment will accumulate along the river, causing bed sedimentation, floodplain aggradation, or abrupt lateral channel movement across the floodplain.

The natural flow regime refers to the characteristics of the hydrograph prior to intensive human alteration of a watershed (Poff et al., 1997) and is commonly described in terms of the magnitude, frequency, duration, timing, and rate of change of flow.

Fig. 2 Schematic illustration of how external inputs in the form of water, sediment, and large wood interact with the valley context to drive reach-scale response variables of river form and process.

Numerous methods exist for quantifying how much an altered watershed deviates from the natural flow regime (Richter et al., 1996; Poff et al., 2010).

Sediment entering the river corridor can serve multiple functions. Sediment in transport requires a minimum level of flow energy to remain mobile, but also acts as a tool to erode the channel bed and banks through abrasion if the sediment is sand-sized or larger (Sklar and Dietrich, 2004). High concentrations of suspended sediment can increase the viscosity of the stream flow and dampen turbulence and erosion (Kuhnle, 2013), and large amounts of coarse sediment supplied to the river corridor can exceed river transport capacity and form a depositional layer that covers the bed and protects underlying sediment and bedrock from erosion (Sklar and Dietrich, 2004). Sediment can come from adjacent uplands and enter the river corridor in abrupt, episodic mass movements such as landslides (Benda, 1990; Korup, 2013). Sediment can also move into the river corridor in a more gradual, diffuse fashion with widespread surface runoff or tributary inputs. Finally, sediment can be remobilized within the river corridor from the stream bed, banks, in-channel bars, and floodplain with subsequent increase in water discharge.

The natural sediment regime refers to the characteristics of sediment inputs, transport, and storage prior to intensive human alteration of a watershed (Wohl et al., 2015). Metrics for quantifying deviation from the natural sediment regime do not yet exist because of the extremely limited direct measurements of sediment transport and the greater difficulty in characterizing sediment inputs and transport relative to river discharge. Wohl et al. (2015) suggest focusing on a balanced sediment regime that involves managing for a desired balance between sediment supply and transport capacity in order to maintain specific physical processes and forms within the river corridor (Wilcock et al., 1996; Schmidt and Wilcock, 2008).

Large wood is recruited to the river corridor from uplands via hillslope failure (Abbe and Montgomery, 2003; May and Gresswell, 2003) and from floodplain forests via individual tree fall or mass mortality during blowdowns, insect infestations or blight, wildfires, and bank erosion (Benda and Sias, 2003). Once in the river corridor, large wood increases resistance to flow (Curran and Wohl, 2003; Hygelund and Manga, 2003) and creates obstructions that enhance hyporheic exchange (Hester and Doyle, 2008; Sawyer et al., 2011). Flow deflection around the wood drives local scour of the bed and banks, but also deposition of finer sediment and particulate organic matter in areas of lower velocity associated with the wood (Battin et al., 2008; Beckman and Wohl, 2014). Particulate organic matter ($>0.45 \mu\text{m}$ in size) is composed of materials such as fragments of leaves and twigs. Scour and deposition around large wood increase the abundance and diversity of aquatic habitat for a variety of organisms (Richmond and Fausch, 1995; Johnson et al., 2003). Logjams, in particular, facilitate formation of multithread channels (O'Connor et al., 2003; Wohl, 2011; Collins et al., 2012) and enhance channel-floodplain connectivity and patterns of overbank erosion and deposition (Jeffries et al., 2003). Floodplain large wood also influences flow resistance and patterns of erosion and deposition during overbank flows, as well as providing vital habitat for diverse types of plants and animals during periods of floodplain inundation and emergence.

A key point in understanding interactions in natural rivers is recognizing that the balance among flow energy, sediment supply, large wood, and channel erosional resistance changes across space and through time.

Biological

River ecologists conceptualize coupling between the physical environment and biotic communities via several means such as examining recovery of populations from disturbance, variation in community structure (the abundance and diversity of plants or animals living in a particular place), connectivity as a constraint on migration and dispersal of organisms, water quality, and sources of energy fueling metabolism. Food webs provide a means to link these topics. Food webs describe the processes by which solar energy is initially captured through photosynthesis and then transferred among organisms through herbivory, parasitism, and predation. Within river channels, energy flows among organisms start with either autochthonous or allochthonous production. Autochthonous production occurs within the channel via photosynthesis by bryophytes (mosses and lichens), attached algae, planktonic algae, and floating or rooted angiosperms (Ward, 1992). Allochthonous production is based on organic detritus from outside the channel in the form of dissolved and particulate organic matter. Much of this organic matter entering the channel comes from leaf litter and wood derived from terrestrial plants. Once in the stream, microbes, fungi, and aquatic invertebrates decompose this organic matter. In small streams, terrestrial organic matter can provide the basis for most of the animal production (the accrual of animal biomass over time) occurring within a stream (Wallace et al., 2015). Within floodplains, energy flows also start with allochthonous production by riparian terrestrial or wetland vegetation, although autochthonous inputs of dissolved and particulate organic matter during overbank floods can be very important (Fig. 3).

The primary consumers of organic matter within a channel are microbes living in biofilm assemblages, macroinvertebrates, and fish. Biofilms composed of attached algae, bacteria, fungi, protozoans, and micrometazoans (Lock et al., 1984) coat solid surfaces within the channel. Biofilms are of particular importance to stream food webs because they drive crucial processes within river ecosystems such as the cycling of organic matter and primary production (Battin et al., 2016). Many animals, such as aquatic invertebrates, specialize in scraping and consuming biofilms (Cummins, 1973; Benke and Jacobi, 1994).

Macroinvertebrates include aquatic insects, crustaceans, mollusks, leeches, amphipods, and nematodes, which collectively typically constitute 98% of animal biomass within the channel of some rivers (Ward, 1992). Different macroinvertebrate assemblages occupy the hyporheic zone, the streambed, the water column, and the air-water interface. Similarly, different species of fish, amphibians, or other aquatic organisms, or different life stages of a single species, occupy different portions of the river corridor.

Primary consumers of organic matter in the floodplain include terrestrial organisms and aquatic macroinvertebrates and fish that live within floodplain water bodies or migrate onto the floodplain during overbank flooding. Primary consumers also include species that live within the river corridor (e.g., beaver [*Castor canadensis* in North America, *Castor fiber* in Eurasia]) and those that move in and out of the river corridor (e.g., moose [*Alces alces*] or waterfowl).

Although distinctive biotic communities occupy hyporheic, channel, floodplain, and upland environments, the boundaries between these environments are leaky, with continual exchanges of matter and energy. Ecologists describe these exchanges as subsidies between aquatic and terrestrial environments. Examples include organic litter entering a channel or floodplain lake from the surrounding riparian forest (Cuffney, 1988); aquatic insects emerging from a water body, which are then eaten by riparian

Fig. 3 Schematic illustration of a riverine food web for rivers in the Southern Rocky Mountains of Colorado, USA.

spiders or birds (Baxter et al., 2005); terrestrial insects such as wasps or ants that are eaten by fish (Nakano and Murakami, 2001); deer (*Odocoileus* spp.) that move into riparian zones to graze; and salmon (*Oncorhynchus* spp.) that migrate upstream to spawn and die, thereby transporting substantial nitrogen from the ocean to the river corridor via their decaying bodies (Gende et al., 2002).

A More Complete View of Rivers: Integrating Physical, Chemical and Biological Processes

Important examples of integrative river characteristics that combine physical and biological aspects are river integrity, connectivity, complexity, and context.

Physical integrity for rivers refers to a set of active river processes and landforms such that the river corridor adjusts to changes in water and sediment inputs within limits of change defined by societal values (Graf, 2001). Ecological integrity describes the ability of the river corridor to support and maintain a community of organisms with species composition, diversity, and functional organization similar to those within natural habitats in the same region (Parrish et al., 2003). River integrity combines these two definitions to describe the ability of the river ecosystem to adjust to changing water, wood, and sediment inputs (without constraints imposed by human manipulation such as dams or levees) and through these adjustments to maintain the habitat, disturbance regime, and connectivity necessary to sustain native biotic communities.

Connectivity describes movements of energy, material, and organisms between components of a system, which are typically spatially defined areas (Wainwright et al., 2011). Connectivity can be characterized in terms of spatial extent, magnitude, duration, timing, and frequency (Fig. 4). Connectivity also implies the presence of disconnectivity, some degree of which is important to many river ecosystem functions and communities. Downstream disconnectivity created by obstructions such as logjams, for example, can help to create fish habitat, retain particulate organic matter and nutrients, and promote fluxes of water between the surface and the hyporheic zone. Disconnectivity may also impede invasions of exotic organisms along river corridors (Rahel, 2013).

A river corridor has three primary dimensions of connectivity both within the corridor and between the corridor and adjacent environments (Ward, 1989; Pringle, 2001). Longitudinal connectivity describes the downstream movement of water, solutes, sediment, organic matter, and organisms, as well as upstream movement by animals (Vannote et al., 1980; Cote et al., 2009). Lateral connectivity can be bi-directional within the river corridor as high flows spread from the main channel into secondary channels and across the floodplain, and then recede back to the main channel (Junk et al., 1989). Lateral connectivity can also be unidirectional as materials and organisms move from uplands into the river corridor or when adult aquatic insects emerge from streams and disperse to riparian habitats. Vertical connectivity is also bidirectional above and below the river and floodplain. Water, gases, and organisms move upward into the atmosphere (Ward, 1989; Raymond et al., 2013). Wet and dry atmospheric deposition, as well as terrestrial insects, move downward into the river corridor. Water, solutes, microbes, and macroinvertebrates move vertically between the

Fig. 4 Illustration of the five major components of hydrologic connectivity within a river corridor.

Fig. 5 Schematic illustration of the three primary dimensions of riverine connectivity. Longitudinal connectivity describes downstream movement of materials and upstream-downstream movements of organisms. Lateral connectivity refers to movement of material and organisms from uplands into the river corridor and between the channel and floodplain and riparian zone within the river corridor. Vertical connectivity describes movements between the river corridor surface and either the atmosphere or the underlying hyporheic zone and groundwater.

channel and the hyporheic zone, and water and associated solutes move vertically between the river corridor and the ground water (Fig. 5) (Brunke and Gonser, 1997).

Complexity has at least two meanings within river science. The first refers to natural systems that exhibit properties such as nonlinear dynamics, in which the change of the output is not proportional to the change of the input (Werner and McNamara, 2007; Phillips, 2014). The second uses complexity to describe spatial heterogeneity, or the degree to which a river corridor deviates from a straight, uniform canal (Wohl, 2016). Spatial heterogeneity in a river corridor occurs at diverse spatial scales from a channel unit or patch of sediment up to the entire longitudinal profile or river network (Fig. 6) (Frissell et al., 1986). At any of these scales, heterogeneity results from discrete patches with differing characteristics. These patches can be described in terms of patch richness (the number of patches present), patch frequency (the number of each patch type), patch configuration (patch arrangement in space relative to each other), patch change (which patches change and how they change), and a shifting mosaic (patch changes are spatially explicit and quantified) (Cadenasso et al., 2006), as well as spatial statistics and other metrics (Wohl, 2016).

Complexity is important for at least five reasons. (1) Complexity in the form of habitat diversity can correlate with biodiversity. Although other factors can constrain biodiversity, greater habitat diversity in river corridors correlates with greater biodiversity and biological productivity (Scott et al., 2003; Luck et al., 2010; Bellmore and Baxter, 2014; Greene and Knox, 2014). (2) Complexity attenuates downstream fluxes of water and elements. Diverse forms of complexity increase hydraulic resistance, reduce average downstream velocity, enhance hyporheic exchange, and facilitate at least transient deposition of organic matter and sediment (Jeffries et al., 2003; Brummer et al., 2006; Ensign and Doyle, 2006; Westbrook et al., 2006; Gooseff et al., 2007; Small et al., 2008; Wohl and Scott, 2017). (3) Complexity influences the resistance and resilience of river corridors to disturbance. A more complex river corridor can be more resistant and resilient to disturbance (Wohl, 2011; Collins et al., 2012). (4) Complexity both reflects and influences processes in rivers. The spatial heterogeneity present in the river corridor reflects the combined history of hydraulic force, sediment movement, and biotic colonization through time (e.g., Choné and Biron, 2016). Complexity influences river processes when bedforms or instream wood increase hydraulic resistance, which in turn influences hydraulic force and sediment movement (e.g., Yochum et al., 2012), or when logjams abandoned during channel migration and then buried in the floodplain form erosionally resistant points that limit subsequent channel migration (Collins et al., 2012). (5) Complexity reflects the inherent unevenness through time and space of processes within a drainage basin and river corridor, as indicated by the presence of ecosystem control points, that is, landscape features that disproportionately affect overall biogeochemical rates at certain times (Bernhardt et al., 2018).

Context refers to the environmental setting of the river corridor. Examples include the climate and precipitation regime, geology, topography, biome, position in the river network, land use, and land use history. Numerous classification systems have been proposed for rivers in recognition of these differences. Ecoregions, process domains, and river styles are examples of classification systems that are applied at relatively broad spatial scales within or between river networks. An ecoregion is a relatively large area of

Fig. 6 Diverse spatial scales of heterogeneity within a river network. At the network scale, valley geometry can vary downstream between wide, low gradient reaches (upper left photo in right column) and narrow, steep reaches (upper right photo in right column). The map at upper left illustrates reach-scale variations in valley geometry: red indicates steep, narrow reaches; yellow indicates intermediate values; green indicates wide, low gradient reaches. The longitudinal profile of a river commonly includes heterogeneity associated with steeper reaches, including waterfalls. Channel planform can also vary downstream between straight, meandering, braided, and anastomosing patterns (yellow arrow in photo indicates flow direction). At the reach scale, cross-sectional geometry can vary between pools and riffles or straight segments and meander bends. The type and dimensions of bedforms present also vary among reaches. At smaller spatial scales, bank irregularities and patches of different streambed grain size create heterogeneity at the channel unit scale.

land or water that contains a geographically distinct assemblage of natural communities (WWF, 2013). Process domains (Montgomery, 1999) and river styles (Brierley and Fryirs, 2005) describe spatially discrete and internally homogenous portions of a landscape or river network characterized by distinct suites of geomorphic forms and processes (Fig. 7).

Ecological Relationships

Disturbance, Resistance, and Resilience

Inputs of matter and energy to a river corridor change through time and the river ecosystem responds to these changing inputs. Disturbance regimes characterize these fluctuations in inputs and resistance whereas resilience characterizes the nature of river ecosystem response.

A disturbance is any relatively discrete event in time that alters ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment (White and Pickett, 1985). A flood is the preeminent example of a disturbance within a river ecosystem. Physical disturbances such as an annual flood commonly maintain habitat abundance and diversity and river connectivity that influence the survival of plants and animals in the river ecosystem (Junk et al., 1989; Bayley, 1991; Naiman et al., 1988b).

The disturbance regime is the spatial pattern and statistical distribution of disturbances with respect to magnitude, frequency, and duration of associated changes in the physical environment (Montgomery, 1999). Disturbance regime in river corridors reflects sources of water, sediment, nutrients, and other materials that originate outside of the river corridor, as well as disturbances within the river corridor. The characteristics of a disturbance and the response of the river corridor to the disturbance also vary within the river network in relation to spatial variations in disturbance and to the valley and channel geometry and substrate erosional resistance.

In a geomorphic context, resistance describes the ability of channel and floodplain substrate to remain physically unchanged by erosion or deposition. In an ecological context, resistance describes the ability of a river ecosystem to remain unchanged following a disturbance (Webster et al., 1975). Resilience is the persistence of the river ecosystem and the ability of populations and processes to return to initial conditions following a disturbance. Physical scientists also use resilience or sensitivity to describe the ability of a river corridor to return to its pre-disturbance configuration following disturbance (Brunsden and Thornes, 1979; Bull, 1991; Wohl, 2010; Reid and Brierley, 2015; Fryirs, 2016). In an ecological context, a resistant river corridor undergoes little change during disturbance and a resilient river corridor returns to its pre-disturbance configuration and relationships over a shorter time than the return interval of the disturbance.

Fig. 7 An illustration of different river styles and characteristics common to headwater, mid-catchment, and lowland plain portions of a river network. In the description of characteristics, CPOM refers to coarse particulate organic matter (>1 mm in size) and FPOM (0.45 μm to 1 mm in size) refers to fine particulate organic matter. After Brierley, G. J. and Fryirs, K. A. (2005). *Geomorphology and River Management: Applications of the River Styles Framework*. Oxford: Blackwell, Figure 2.10.

An important aspect of understanding resistance and resilience is to explicitly recognize that physical characteristics of the river corridor and biotic communities are adjusted to the natural range of variability (Keane et al., 2009) in water, sediment, and large wood fluxes through time. For a river corridor, the natural range of flow variability, for example, describes the upper and lower magnitude limits of discharge, as well as the range of duration, frequency, rates of change, and seasonal timing of various components of the hydrograph in the absence of substantial human alteration of the watershed or manipulation of the flow (Poff et al., 1997).

Conceptual Models

River scientists use conceptual models to illustrate and explore interactions between physical processes and biotic communities and to describe patterns observed within river networks. Geomorphic conceptual models emphasize change through time, particularly in response to disturbances. These models include positive or self-enhancing feedback that occurs when an initial change creates a cascade of subsequent changes that amplify the initial change. These models also account for negative or self-arresting feedback that occurs when the response of the river corridor dampens an initial change. Response of the river corridor can lag changes in inputs, and change commonly occurs in an abrupt, nonlinear manner described via thresholds that separate distinct forms or modes of operation of a system. External thresholds refer to change forced by an external factor such as a flood, whereas internal or intrinsic thresholds describe abrupt changes in a river corridor in the absence of external change (Schumm, 1979).

When change occurs within morphologic features such as channel bars or floodplain wetlands, the affected morphologic feature can be described as transient or persistent (Brunsdon and Thornes, 1979; Bull, 1991). A transient form is created by a disturbance, but then returns to pre-disturbance conditions before the recurrence of a disturbance of similar magnitude. A persistent feature remains past the recurrence interval of the disturbance that created the feature. River metamorphosis describes an abrupt, sustained change in river form (Schumm, 1969; Wohl, 2013).

The most widely used river ecology conceptual models emphasize one of three characteristics: longitudinal patterns of process and form; lateral connectivity within river corridors; and changes through time. The river continuum concept (RCC) first described longitudinal patterns (Vannote et al., 1980). The RCC posits progressive downstream changes in the relative importance of primary production versus respiration and in the structure and function of aquatic communities (Fig. 8). Ward and Stanford (1983, 1995)

Fig. 8 Schematic illustration of the downstream changes in the relative importance of primary production (P) versus respiration (R) and in the structure and function of aquatic macroinvertebrate communities (shredder, grazer, predator, collector refer to functional groups of aquatic macroinvertebrates). After Vannote, R. L., Minshall, G. W., Cummins, K. W., Sedell, J. R. and Cushing, C. E. (1980). The river continuum concept. *Canadian Journal of Fisheries and Aquatic Sciences* **37**, 130–137, Figure 1).

describe a variation in these downstream trends associated with the presence of dams and reservoirs that reset the downstream patterns, as described in the serial discontinuity model. Other studies emphasize hierarchical patch dynamics, which characterizes river corridors as consisting of relatively homogeneous patches from the scale of microhabitat up to channel reaches, with distinct changes in process and form between patches (Pringle et al., 1988; Poole, 2002; Thorp et al., 2006).

Longitudinal patterns of process can also be described in the context of nutrient spiraling. Nutrients such as nitrogen and phosphorus are displaced downstream as they complete a cycle (Webster and Patten, 1979) through the generalized compartments of water, particulates, and consumers (Newbold et al., 1981). Spiraling length refers to the downstream distance required for one complete cycle or, in the case of organic carbon, as the distance between its entry into the river corridor and its oxidation (Elwood et al., 1980). Spiraling length reflects the use of nutrients relative to the available supply as well as physical characteristics of the river corridor, such as the ability to at least temporarily retain solutes and particulates in areas of reduced transport capacity (Fisher et al., 1998; Battin et al., 2008; Baker et al., 2012).

Lateral connectivity within river corridors is the focus of the flood-pulse model (Junk et al., 1989), which describes the ecological influence of the seasonal flood pulse on large floodplain rivers such as the Amazon (Fig. 9). Water, sediment, nutrients, and organisms move from the channel onto the floodplain during peak flood flow and then return to the main channel and secondary channels during the receding limb and base flow. This repeated movement enhances nutrient availability, as well as habitat and biodiversity within the channel and the floodplain. A subsequent iteration of this model emphasizes flow pulses, which are smaller-scale fluctuations in discharge that change the extent of flow and standing water within a braided or multithreaded channel segment as well as flow levels along the margins of bars and islands within channels (Tockner et al., 2000).

Changes through time have been conceptualized in terms of river resistance and resilience, as described previously, and in terms of alternative states. Alternative stable states describe ecological systems that can exist in multiple, distinct, and self-reinforcing states in equilibrium under equivalent environmental conditions (Holling, 1973; May, 1977; Carpenter, 2003). This scenario relies on a disturbance or a threshold in response to ongoing changing conditions that is capable of driving the ecosystem into a new state from which it will not return. The ecosystem then takes a different pathway of recovery in response to the disturbance, which ultimately leads to a self-sustaining reorganization of ecosystem structure. The existence of alternative stable states has typically been

Fig. 9 Schematic illustration of the flood-pulse cycle and the associated lateral connectivity between the channel and floodplain. After Junk, W. J., Bayley, P. B. and Sparks, R. E. (1989). The flood-pulse concept in river-floodplain systems. *Canadian Special Publications in Fisheries and Aquatic Sciences* **106**, 110–127, Figure 2.

evaluated based on biotic community structure (e.g., Scheffer and Carpenter, 2003), although the concept is controversial because of the difficulty in demonstrating long-term stability (Schröder et al., 2005). This has led to the related concept of alternative states, which can be stable or transient over varying time scales (Suding et al., 2004).

Commercial Uses

The primary commercial uses of river channels include navigation, waste disposal, hydroelectric power generation, water storage, commercial fisheries, aggregate and placer mining, and diverse recreation (e.g., boating, fishing). Primary commercial uses of floodplains and riparian zones include agriculture and urbanization, which are commonly accompanied by land drainage and changes in land cover within the floodplain. These uses all have the potential to modify river corridors and the modifications can be categorized as consumptive/depletive (e.g., removal of water or organisms) or destructive (e.g., channelization or pollution) over diverse scales of time and space (Fig. 10), although human communities can benefit from these uses. The magnitude of physical and ecological changes resulting from individual commercial uses depend on factors such as the magnitude and duration of the commercial activity. Navigation, for example, can substantially alter river form, function, and process if the navigation is accompanied by channelization (channel straightening, dredging, bank stabilization, and levee construction) and if numerous large vessels generate waves that erode river banks and alternately expose and inundate portions of the river banks (Fig. 11) (Nanson et al., 1994).

The cumulative effects of diverse commercial uses have been to homogenize and simplify river corridors and to alter their connectivity. Dams and water diversions homogenize naturally variable flow regimes (Poff et al., 2007). Dams also fragment river networks thereby disrupting reproductive migrations of native fishes. Levees and channelization limit lateral connectivity between channels and floodplains and vertical connectivity between the surface and the hyporheic zone (e.g., Chovanec et al., 2004). These physical changes are reflected in massive loss of freshwater biodiversity and homogenization of river biota (Moyle and Mount, 2007; Peipoch et al., 2015). Within the United States, fewer than 2% of total river kilometers remain unaltered by flow regulation (Graf, 2001). More than half of the world's large river systems are altered by dams (Nilsson et al., 2005). Because of a long history of intensive and extensive commercial uses, river ecosystems can be regarded as a globally endangered ecosystem.

Fig. 10 Diverse types of consumptive and destructive commercial uses of the channel and floodplain/riparian components of river corridors. Any of the consumptive uses can become destructive if they are conducted in an unsustainable manner.

Channelization of a small channel in an agricultural region of Switzerland (upper right). Untreated urban sewage flowing into a river in Bogota, Colombia (lower right). Dry channel exposed downstream from a dam along the Vindel River in northern Sweden (lower left).

Major Anthropogenic Threats

Anthropogenic threats to river corridors include direct threats from activities occurring within the river corridor (e.g., channelization and flow regulation) and indirect threats from activities outside the river corridor that influence inputs of water, sediment, solutes, and large wood to the river corridor (e.g., changes in land use).

Habitat Modification, Fragmentation, and Destruction

River corridor habitat is modified, fragmented, and destroyed by most commercial uses. Channelization, levees, and bank stabilization simplify spatially heterogeneous channels and commonly increase longitudinal connectivity while reducing lateral

and vertical connectivity. Dams and diversions alter the fluxes of water and sediment that not only facilitate connectivity within river corridors, but also maintain habitat diversity. Floodplain drainage and changes in land cover within floodplains fragment or destroy floodplain habitat and connectivity. In-channel structures such as culverts, grade controls, and bridges alter channel geometry and stability and can limit aquatic organism passage (Cenderelli et al., 2011). Loss of headwater streams that are buried in pipes in both agricultural and urban areas significantly alters downstream fluxes of material and reduces habitat diversity for aquatic and riparian organisms (Fig. 12) (Elmore and Kaushal, 2008). Removal of instream large wood and beavers reduces habitat abundance and diversity, as well as lateral and vertical connectivity within river corridors (Naiman et al., 1988a, b; Burchsted et al., 2010; Pollock et al., 2014; Roni et al., 2014).

Mitigation strategies for habitat modification and fragmentation include: allowing rivers sufficient space to continue to adjust to changing water and sediment inputs by setting back levees and limiting infrastructure and urban encroachment on the river corridor (Dierauer et al., 2012); creating environmental flows that sustain longitudinal connectivity and habitat diversity (e.g., Opperman et al., 2018); and either actively reintroducing or allowing natural reintroduction of large wood and beavers to river systems (e.g., Pollock et al., 2014).

Invasive Species

Both aquatic and riparian invasive species can significantly modify river corridors in ways that reduce habitat and resources for native species, as well as directly competing with native species. Invasive plants in riparian zones can displace native species (Stromberg, 1998) and alter river morphology; for example, the invasion of tamarisk trees (*Tamarix* spp.) to riparian zones in rivers in arid regions can reduce channel width (Graf, 1978) and limit the lateral channel movement that creates habitat heterogeneity in the channel and floodplain. Invasive animals can change the aquatic food web, as in the example of invasive nonnative rainbow

Fig. 12 An example of stream burial. Here, a tributary draining the mountains adjacent to the city of Bogota, Colombia is diverted into a pipe before entering the city limits.

trout (*Oncorhynchus mykiss*) in Japan that usurped terrestrial insects falling into a stream, thereby causing native Dolly Varden charr (*Salvelinus malma*) to shift their foraging to insects grazing algae from the stream bed (Baxter et al., 2004). This indirectly increased algal biomass and decreased the biomass of adult aquatic insects emerging from the stream. Reduced insects entering the forest from the stream caused a decrease in riparian-specialist spiders in the forest.

The effects of animal invasions on streams are varied, ranging from having little effect to greatly affecting other animal populations via predation (Cucherousset and Olden, 2011) or interbreeding (Allendorf et al., 2001). Some invasive animal species in rivers can have extensive ecosystem-level effects due to high biomass of the invaders relative to native animals (Caraco et al., 1997; Hall et al., 2003). Past responses to invasive species have included attempted eradication; blocking migration routes; raising public awareness of, and attempting to limit, inadvertent human spread of invasive species; introducing other species that prey on or parasitize the original invasive species; and restoring riverine structure and function in a manner that favors native species. These responses can help, but there has been little success with completely eradicating invasive species once they are established in a river.

Environmental Pollution

As sites of concentrated human activity, river corridors receive diverse forms of pollutants. Major categories include heavy metals, mercury, nitrogen, phosphorus, pathogens, various persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs) and pesticides, and sediment. Heavy metals such as Pb, Cu, and Zn are toxic to many aquatic animals, particularly invertebrates, and originate from natural and anthropogenic sources such as metal-rich mineral deposits, mining, chemical industries, fossil fuel combustion, and sewage waters (Bednarova et al., 2013). Mercury is a highly toxic natural element that enters rivers primarily via atmospheric emissions of inorganic mercury from coal combustion, waste incineration, and wildfire, as well as via discharge of industrial and municipal wastes (Fisher et al., 2012).

Nitrogen (Green et al., 2004; Galloway et al., 2004; Boyer et al., 2006) and phosphorus (Withers and Jarvie, 2008) become river pollutants at concentrations exceeding those of natural or background levels. This causes eutrophication, where high nutrients stimulate growth of algae and other aquatic plants. Excessive plant growth increases organic loading to rivers, which can in turn lead to oxygen depletion and animal die-offs (Mallin et al., 2006). Excess nitrogen and phosphorus result from agricultural and urban runoff, and nitrogen is also increased by fossil fuel emissions.

Pathogens include any microbial organism that can impair the health of humans or other organisms. Pathogens enter rivers from wastewater treatment effluent, sewage tanks, and agricultural operations, particularly those involving livestock (Varela and Manaia, 2013).

Persistent organic pollutants (POPs) are organic chemicals produced for a variety of agricultural and industrial uses. These chemicals are persistent because they degrade very slowly via natural processes and thus incur a long-term legacy of potential environmental exposures and effects. Many of these compounds are lipophilic ("fat loving") causing them to bioaccumulate in organisms and to biomagnify to potentially toxic levels in food webs (Walters et al., 2016). Polychlorinated biphenyls (PCBs), for example are a large class of persistent organic pollutants (POPs) that were widely used as additives in oils, industrial fluids, and other commercial products. PCBs cause a variety of health effects including cancer and remain one of the leading causes of organic pollution in riverine environments even though their production was banned in 1979 (National Research Council, 2001; USEPA, 2011). Other common types of organic pollutants in rivers include pesticides, polyaromatic hydrocarbons (PAHs), and brominated flame retardants among many others (Walters et al., 2016).

Mitigation strategies for pollutants include creating and enforcing water quality standards (e.g., Boyd, 2015); aggressively remediating contaminated sites (e.g., Sheng et al., 2013); and restoring and protecting riparian zones and in-channel heterogeneity that facilitate retention and biological uptake of excess nutrients (e.g., Aguiar et al., 2015). Sediment of sand size or smaller can be a pollutant in rivers because the sediment may carry adsorbed contaminants or because the sediment creates adverse impacts on water and channel properties. Adverse impacts include increased turbidity (a loss of water clarity) and the clogging of spaces between rocks on the stream bed that are important habitats for the survival of stream invertebrates, fish eggs, and some fishes. Excessive sediment deposition can lead to a loss of pool habitats themselves, which are also important habitats for many aquatic organisms. Beyond these obvious and direct effects on river habitats and organisms, excessive sediment increases the costs of drinking water treatment and stimulates growth of cyanobacteria that can produce chemicals toxic to other organisms. Owing to the myriad and pervasive negative effects of sediment on river ecosystems, the US Environmental Protection Agency lists sediment as the most common river pollutant (Owens et al., 2005). Mitigation strategies for pollution associated with excess fine sediment include protection and restoration of riparian zones that can retain fine sediment and enforcement of best management practices for construction, timber harvest, agriculture, and other activities that can result in erosion of fine sediment from uplands and transport into river systems (e.g., Aust and Blinn, 2004).

Climate Change

The details of climate change vary with geographic location, but changing climate affects the entire landscape and thus inputs of water, sediment, solutes, and large wood to river corridors, as well as transport and storage of material within the river corridor. These changes will in turn affect habitat abundance and diversity, disturbance regime, and connectivity within the river corridor. Climate warming is likely to disproportionately affect animals that depend upon cold-water habitats such as Bull Trout (*Salvelinus confluentus*) and the American Dipper (*Cinclus mexicanus*). These types of species will experience shrinking geographic ranges and

limited dispersal opportunities as the climate warms (Rieman et al., 2007). These effects are already apparent for certain cold-water taxa like high-alpine insects that are dependent upon glacial melt-water streams (Giersch et al., 2017). Climate warming is also likely to severely impact aquatic and riparian species in arid and semiarid regions, where the combined effects of decreasing precipitation and increasing human consumptive demands for water will lead to progressive drying of river corridors (Falke et al., 2011).

Changing climate can alter human consumptive demand, such as when depletion of groundwater aquifers and increasing drought result in greater water diversion from rivers. Finally, changing climate can increase hazards such as flooding, triggering additional human modifications of river corridors to enhance flood risk reduction.

Climate change is ongoing, but mitigation strategies for river systems can focus on: protecting connectivity that allows organisms to disperse to more suitable locations (Rahel et al., 2008), and on protecting and restoring characteristics that increase the resiliency of the river system to climate-associated disturbances such as floods, droughts, and wildfires. Restoring beaver populations and the high water tables and dense woody riparian vegetation that commonly accompanies beaver ecosystem engineering, for example, can help to mitigate the effects of droughts and wildfire (Hood and Bayley, 2008).

Conservation and Management

Traditional river management seeks to minimize natural disturbances and to constrain a river's ability to adjust its form in response to disturbance. This approach has harmed river biotic communities to the point that river management in many cases now seeks to restore disturbances, spatial heterogeneity, and diverse forms of connectivity (Wohl et al., 2015). Management and restoration of river corridors occur within the context of legal frameworks associated with legislation such as the 1972 Clean Water Act and the 1973 Endangered Species Act in the United States and the European Union's 2000 Water Framework Directive, each of which mandates levels of protection for water quality, habitat, and individual species. The Clean Water Act, for example, has been credited with substantial improvements in riverine water quality through regulation of point-source discharges, such as municipal water-treatment plants (EPA, 2000).

Research Needs

Among the primary research needs to enhance understanding and protection of river ecosystems are continued development of methods that quantify natural flow, sediment, and wood regimes, as well as necessary levels of restoration or mitigation where these regimes have been substantially altered. Bernhardt and Palmer (2011), for example, call attention to the fact that restoring riparian corridors along limited portions of a river network is unlikely to create enough retention and biological uptake of nitrogen to mitigate watershed-scale increases in nitrate inputs to river systems. Analogously, addition of a limited number of engineered logjams is unlikely to effectively mitigate historical river metamorphosis in which wood removal changed multi-channel, laterally mobile rivers with heterogeneous channels and floodplains to single-channel, laterally stable rivers with less habitat diversity (Collins et al., 2002). Mitigating changes to natural flow, sediment, and wood regimes also requires understanding how disturbances create and maintain desirable ecological processes and functions. The widespread tendencies to attempt to suppress natural disturbances such as floods or wildfires or to immediately reverse some of the effects of these disturbances (e.g., channel engineering designed to simplify channels and remove the habitat diversity created by flooding) suggest the need both to increase societal awareness of the importance of natural disturbances and to enhance scientific understanding of minimum thresholds of disturbance required to maintain the ecological integrity of river systems. We also need to develop methods allowing us to predict biotic responses to geomorphic changes in river form. This point is intentionally broad, in that what we need to predict depends on the research question or management objective. Predicting the response of species richness to river change is an example of a well-researched topic with obvious implications for river conservation (Hawkins et al., 2000). Some restoration efforts do not have the expected impact on biotic structure, e.g. increasing temperatures below a cold-water release dam did little to restore native invertebrate diversity (Vinson, 2001). Other approaches might be to predict ecosystem processes such as metabolism following river alteration or restoration (Bernhardt et al., 2018).

Abstract

Riparian ecosystems encompass a diverse suite of ecosystem types, including river banks, floodplains, and wetlands, that are characterized primarily by being ecotones, or transitional zones, between adjacent terrestrial and aquatic realms. In general, riparian ecosystems represent wetter, cooler, and more heterogeneous habitats than adjacent upland areas and consequently tend to support biologically distinctive, productive and diverse communities. Riparian ecosystems also provide a wealth of critical ecosystem functions and services of importance at local and catchment scales. In particular, riparian vegetation plays a key role in: regulating microclimates and water quality; preventing riverbank erosion and promoting landform stability; subsidizing aquatic and terrestrial food webs; and providing habitat for a wide range of aquatic, amphibious, and terrestrial organisms. Despite these values, riparian ecosystems are also some of the most altered, degraded and vulnerable ecosystems on Earth, due largely to their position in the landscape and hotspots of intensive human activity. Effective management and restoration of riparian ecosystems is increasingly urgent, for both the conservation of much terrestrial and aquatic biota and the wellbeing and livelihoods of people throughout the world. Management approaches range from protection of intact riparian ecosystems to active revegetation of degraded riparian zones. Significant knowledge gaps exist in many places, however, regarding relationships between riparian ecosystem structure and function and the responses of these to disturbances and management interventions.

What Are Riparian Ecosystems?

The term *riparian* is derived from the Latin word *ripa*, meaning river bank. Indeed, riparian ecosystems are often considered to be limited to the relatively narrow borders of rivers and streams, e.g., gallery forests or fringing wetlands. In ecological terms, however, riparian ecosystems comprise a much broader suite of landforms that are characterized primarily by being zones of transition between terrestrial and aquatic (excluding marine) realms, the latter of which may comprise either lotic (i.e., flowing) or lentic (i.e., standing) waters (Naiman et al., 1998; Nilsson and Svedmark, 2002). As such, riparian ecosystems are examples of “ecotones,” i.e., transitions or boundaries between adjacent contrasting biomes (Naiman et al., 2005).

In a functional sense, riparian ecosystems can be defined as those areas which, due to their position fringing watercourses or waterbodies, exert a direct influence on adjacent aquatic ecosystems and, in turn, are themselves influenced by these (Naiman et al., 2005; Capon et al., 2013a,b). Consequently, riparian ecosystems include river and stream banks but also floodplains and the edges of lakes, including littoral zones, and other wetlands. Furthermore, dry river and lake beds as well as dry phases of intermittent wetlands can function as riparian ecosystems whose reciprocal interactions with their associated aquatic ecosystems are separated in time rather than space (Brock et al., 2006).

To some extent, the entire catchment of a watercourse or waterbody might be considered riparian, at least to some degree, in the sense that all areas within these may exert some influence on the aquatic ecosystems which they drain into—the degree of “riparian-ness,” i.e., the types, strength and significance of interactions that occur between neighboring terrestrial and aquatic ecosystems, declining with increasing distance. In practice, however, and particularly from legal and planning perspectives, riparian ecosystems are often only considered to comprise relatively narrow areas of land adjacent to watercourses (Verry et al., 2004).

Features of Riparian Ecosystems

As representatives of a biome that is widely distributed across every continent on Earth, riparian ecosystems are highly diverse, reflecting global and regional variation in climate, geology and geomorphology as well as the enormous range of terrestrial and aquatic ecosystems which they traverse. Because of their common low-lying position within the landscape, however, and the influences of the watercourses or waterbodies which they border, riparian ecosystems generally share numerous distinctive characteristics (Naiman et al., 2005).

First and foremost, riparian ecosystems tend to be wetter than surrounding terrestrial ecosystems. Depending on the permanence of water within adjacent aquatic systems, biota inhabiting riparian zones may have greater access to surface and shallow ground water and higher soil moisture levels. Humidity is also typically higher in riparian ecosystems (Pettit and Naiman, 2007). Additionally, riparian ecosystems are often subject to lower rates of evaporation and cooler temperatures than neighboring upland areas (Broszofski et al., 1997; Danehy and Kirpes, 2000; Dwire and Kauffman, 2003). As ecological edges, however, riparian zones can also have higher levels of light and more exposure to wind, waves and climatic events such as storms, cyclones and storm surge, particularly in areas immediately fringing open watercourses or waterbodies (Capon et al., 2013a,b).

Many riparian ecosystems (e.g., river banks, floodplains) are characterized by intermittent flooding which occurs as a result of overbank flows (Stromberg, 2001; Nilsson and Svedmark, 2002; Capon, 2003, 2005; Poff and Zimmerman, 2010). As well as temporarily increasing the extent and depth of surface waters (and topping up groundwaters), floods redistribute materials within a catchment. Flooding both deposits and scours fresh sediments (and nutrients) from riparian landforms which can consequently be quite dynamic, depending on the hydrological and hydraulic regimes to which they are subject (Gregory et al., 1991; Hupp and Osterkamp, 1996). Furthermore, at a landscape scale, riparian lands typically have more fertile soils than upland areas, at least in depositional areas, e.g., floodplains (Spink et al., 1998).

Flooding, as well as stream flow, provides an additional dispersal vector for propagules known as *hydrochory* (Nilsson et al., 1991). Biota in riparian ecosystems may therefore have more available dispersal vectors than organisms inhabiting terrestrial ecosystems because of the high potential for hydrochory as well as zoochory (i.e., dispersal via waterbirds and other animals that utilize the riparian corridor) and anemochory (i.e., dispersal via wind which may be enhanced by the openness of adjacent watercourses/waterbodies). Riparian organisms are also, however, subject to many stresses during periods of inundation including anoxia and the associated accumulation of toxic materials in the soil, reduced light in submerged areas and burial by deposited sediments (Blom and Voesenek, 1996; Nilsson and Svedmark, 2002; Capon, 2003). Furthermore, swiftly flowing surface waters, during floods as well as other times, can cause mechanical damage to in situ organisms, e.g., by snapping stems or uprooting plants (Bendix, 1999).

Overall, spatial and temporal variation in hydrological regimes across riparian ecosystems generates dynamic mosaics of habitat patches which differ in their availability of resources as well as the presence and intensity of stressors (van Coller et al., 2000; Capon, 2005; Brock et al., 2006). Consequently, riparian ecosystems are usually characterized by a high degree of habitat heterogeneity in space and time, both at local and larger (e.g., catchment) scales (Stromberg et al., 2007). Because of this, as well as their distinctive abiotic characteristics, riparian zones often support highly productive and species rich ecosystems (Capon and Pettit, 2018). In many places, more species occur in riparian ecosystems than in neighboring uplands, although this is not always the case (De'camps et al., 1987; Woinarski et al., 2000; Bennett et al., 2014). For the most part, however, riparian ecosystems enhance biodiversity at landscape and catchment scales by supporting different, if not more, species than surrounding terrestrial ecosystems (Sabo et al., 2005).

Riparian ecosystems typically comprise dynamic assemblages of aquatic, amphibious and terrestrial species, reflecting the range of conditions provided by these areas in space and time. Some species occurring in riparian ecosystems may have much broader distributions and only utilize riparian habitats at certain times or under particular conditions (e.g., aquatic organisms during flooding; King et al., 2003). Other species, however, can be restricted to riparian zones, either in certain locations or throughout their entire ranges (Rood et al., 2010). Such species might be considered to be riparian specialists if they possess traits that enable them to survive and flourish in riparian habitats (e.g., Machtans et al., 1996; Januschke and Verdonschot, 2016). Rheophytes, for example, are a group of plants adapted to swiftly flowing water (van Steenis, 1987).

As well as supporting high levels of biodiversity, riparian ecosystems are often characterized by greater structural habitat complexity than adjacent uplands (Capon, 2005). Riparian vegetation structure in particular tends to be very heterogeneous spatially, typically exhibiting lateral zonation along gradients of distance and/or elevation as a result of variation in exposure to surface water inundation or wave action (Hupp and Osterkamp, 1996; van Coller et al., 2000). Population structures of woody riparian species can similarly display lateral zonation with younger recruits (i.e., seedlings and saplings) often occurring at the edges of watercourses/waterbodies where there is greater exposure to light, soil moisture and freshly deposited, vacant sediments (e.g., Pettit et al., 2001; Boland, 2014).

The lateral extent (i.e., width) and differentiation of riparian ecosystems from the surrounding terrestrial landscape varies considerably both within and between catchments, largely in response to broad scale hydrological conditions. In areas of high precipitation, for example, such as tropical rainforests, riparian ecosystems bordering narrow streams might be relatively indistinguishable from adjacent upland forests, although some differentiation may occur where channels are wider as a result of greater light availability. In contrast, riparian ecosystems in arid landscapes are often very distinct from upland areas, even along narrow watercourses, reflecting marked differences in water availability (Capon et al., 2016a,b). Furthermore, riparian ecosystems in arid regions can support species with distributions that extend as "green tongues" from their more mesic distributions (Selwood et al., 2017). Indeed, in many arid regions, riparian vegetation represents the only major perennial plant life in otherwise relatively barren landscapes. Increasingly, riparian zones also tend to contrast starkly with their surrounding catchments because they are the only areas of significant vegetation remaining in human-dominated agricultural or urban landscapes (James et al., 2016).

Functions and Benefits of Riparian Ecosystems

Riparian ecosystems are critically important at both local and landscape scales and potentially even at much larger scales, e.g., by providing habitat along routes for migratory birds that travel between continents (Table 1; Capon et al., 2013a,b). Riparian vegetation, in particular, supports many key ecosystem functions that underpin ecological patterns and processes both within the aquatic ecosystems which they fringe as well as in the broader terrestrial landscape (Capon and Pettit, 2018). Significant functions of riparian ecosystems include the moderation of light and temperature within adjacent aquatic ecosystems, largely through shading by overhanging canopies, including those of trees, shrubs and herbaceous understorey plants. By reducing light availability, riparian vegetation can contribute to the regulation of aquatic plant growth, including green algae (Chauvet and Decamps, 1989). Shading also lowers water temperatures, providing refuges for aquatic organisms that are vulnerable to high temperatures (Stewart et al., 2013).

Riparian ecosystems serve as important buffers between aquatic ecosystems and their catchments and are therefore vital for regulating water quality (Mayer et al., 2007; Capon and Pettit, 2018; Luke et al., 2019). Riparian vegetation and soils play a particularly significant role by filtering terrestrial run-off and shallow groundwaters from catchments before these enter aquatic ecosystems, trapping sediments and nutrients via the physical presence of vegetation, litter and woody debris, as well as through plant nutrient uptake and soil microbial activity (Lowrance et al., 1984; Pinay and Decamps, 1988; Pinay et al., 1993). Riparian vegetation also has a significant influence on landform stability, especially that of river banks and beds in lotic systems (Malanson, 1993; Hubble et al., 2010; Solari et al., 2016; Krzeminska et al., 2019). Both deep and shallow rooted plants can reduce erosion and increase soil cohesion while surface vegetation and litter cover can protect top soils (Capon and Pettit, 2018). Riparian vegetation can further minimize bank erosion more indirectly by influencing surface water hydraulics, e.g., by roots or stems slowing down swiftly flowing waters (Pollen-Bankhead and Simon, 2010). Inundation patterns (e.g., flood extents) can similarly be affected by riparian ecosystems, especially their vegetation, soils and topography, which may therefore play an important role in flood mitigation and/or protecting upland areas from other disturbances such as storm surge (Capon et al., 2013a,b).

Riparian ecosystems provide significant habitat and food resources for both terrestrial and aquatic organisms, both directly and indirectly (Capon and Pettit, 2018). In aquatic ecosystems, overhanging branches or roots from riparian vegetation can provide vital habitat for a range of organisms (e.g., algae, invertebrates, fish), as can leaf litter or larger woody debris that enters watercourses from their riparian zones. Riparian leaf litter can play a particularly important role in some aquatic food webs where it is consumed by some groups of invertebrates, e.g., shredders (Cummins et al., 1989). In turn, riparian ecosystems support the supply of significant food contributions of aquatic origins to terrestrial food webs, e.g., adult aquatic insects such as dragonflies (Lynch et al., 2002). Because of their accessibility to water and other abiotic characteristics (e.g., lower temperatures), riparian ecosystems represent critical habitat for terrestrial fauna in many landscapes at certain times, e.g., as refuges from drought or heatwaves (Reside et al., 2014). Furthermore, riparian zones may provide corridors for the movement of organisms throughout the landscape, which may be particularly significant under climate change by allowing mobile species to migrate into cooler areas at higher elevations (Krosby et al., 2018).

Many riparian ecosystem functions are of direct benefit to people (e.g., water quality protection, erosion control, recreational values) while many others support crucial regulating ecosystem services (Table 1; Capon et al., 2013a,b). Many riparian ecosystem services (e.g., shading, flood mitigation) are also increasingly recognized as vital in relation to climate change adaptation (Capon et al., 2013a,b). The value of ecosystem services and benefits provided to people by riparian ecosystems is widely considered to be disproportionately high with respect to the surface area which they occupy.

Table 1 Critical ecological functions and associated ecosystem services provided by riparian ecosystems and some major factors influencing these

<i>Ecological functions</i>	<i>Ecosystem services</i>	<i>Key influencing factors</i>
Climatic regulation	Shading, provision of drought and heat refuges	Riparian canopy cover and height, channel width and aspect
Nutrient filtration and cycling	Water quality regulation	Riparian vegetation width and continuity, vegetation composition, root depth and structure, leaf litter, topography, hydrology, soil type
Sediment trapping Stabilization of channel banks and beds	Water quality regulation, landform stability	Riparian vegetation width and continuity, stem density, root structure, leaf litter, topography, hydrology, hydraulics, type of substrates
Food web subsidies Habitat structure	Support of biodiversity, e.g., fish Timber production, pasture growth, support of biodiversity, e.g., fish	Riparian vegetation composition and dynamics, hydrology, water quality Riparian vegetation composition and dynamics, hydrology, other disturbances (e.g., fire), surrounding landscape condition

Major Determinants of Riparian Ecosystem Structure and Function

While the regional species pools from which riparian assemblages are drawn are influenced by many factors, especially climate, the composition and structure of riparian ecosystems are typically governed primarily by hydrology (Power et al., 1995; Poff and Zimmerman, 2010). Riparian vegetation in particular is strongly influenced by hydrology and, to a lesser degree, geomorphology, and soils (Capon et al., 2016a,b). Patterns of water availability, flooding, and drying typically have an overarching effect on the condition, survival, reproduction and interactions of riparian plants and, therefore, the temporal and spatial patterns in vegetation communities of riparian landscapes (Capon et al., 2016a,b). Over short timeframes, key hydrological attributes influencing riparian ecosystems include the timing of flows/floods (e.g., seasonality), duration of flooding, magnitude (depth and extent) of flooding and the rates of rise and fall of floodwaters (Nilsson and Svedmark, 2002). Such factors act as environmental filters determining which species are able to tolerate the stresses generated by flooding and which are best able to capitalize on the associated opportunities for dispersal, growth and reproduction. Over longer time periods, patterns of flow/flood history (e.g., flood frequency) are also important (Capon, 2005). Spatial variation in riparian tree populations, for example, often reflect longer-term patterns in flood history (Friedman and Lee, 2002; Hultine et al., 2007; Stromberg et al., 2010). Many other factors can also exert significant influences on riparian vegetation dynamics depending on the nature of the ecosystems involved, e.g., hydraulics, salinity, fire. In most cases, however, such factors are themselves shaped by hydrological regimes (Capon et al., 2016a,b).

Riparian ecosystem function is strongly influenced, in turn, by the composition, structure and condition of riparian vegetation (Table 1; Capon and Pettit, 2018). Vegetation composition and structure, for instance, influences the presence and quality of habitats types and food resources available. Below ground, root density, architecture and composition affect groundwater filtration, nutrient uptake and landform stability. The width and density of riparian vegetation are particularly important with respect to its role as a buffer with wider, denser and more contiguous riparian vegetation typically having a greater capacity to trap sediments and nutrients (Mayer et al., 2007). Provision of habitat and food resources by riparian ecosystems to both terrestrial and aquatic organisms will also be determined by the extent of riparian vegetation, both laterally and longitudinally, as well as its spatial and temporal heterogeneity. The continuity of fringing riparian vegetation along watercourses, as well as in connection with upland vegetation patches, will especially contribute to its accessibility as refugial habitat for terrestrial fauna and its capacity to provide corridors for the movement of organisms through the landscape.

While riparian vegetation tends to play a fundamental role, complex interactions between hydrology, geomorphology and soils also influence riparian function. Riparian ecosystems with gently sloping landforms, shallow water tables and permeable soils, for example, may have a greater capacity to intercept and filter groundwaters (Mayer et al., 2007). Similarly, the width and orientation of adjacent aquatic landforms can determine the role and importance of some riparian ecosystem functions. The effects of shading by riparian vegetation, for example, might be expected to be more significant in narrow streams, although even partial shading of broad river reaches can provide some thermal refuges for aquatic organisms (Capon and Pettit, 2018).

Because of complex interactions between climate, hydrology and geomorphology, the composition, structure and function of riparian ecosystems vary considerably between regions as well as within catchments (e.g., upper vs. lower reaches) and over time in relation to hydrologic conditions. Furthermore, many riparian ecosystem functions (e.g., provision of drought refuge and corridors for fauna) can be expected to become more significant under climate change (Capon et al., 2013a,b).

Threats and Pressures

Riparian ecosystems are widely considered by to be amongst the most modified and degraded ecosystems in the world (Tockner and Stanford, 2002). Human activities and developments are often concentrated within and surrounding riparian zones in both urban and agricultural landscapes. Consequently, riparian ecosystems are frequently subject to a wide range of direct anthropogenic pressures including vegetation clearing, landform modification (e.g., channelization and armouring), water resources development, draining, harvesting, hunting, forestry, cropping, grazing, and infrastructure development. Many of these pressures result in significant reductions in the extent of riparian vegetation, including its width and longitudinal continuity, as well as changes to vegetation composition and structure with significant implications for critical ecosystem functions and services. Declining water quality in many human-dominated catchments around the world, for example, is often directly attributable to the loss and degradation of riparian vegetation (Sweeney et al., 2004; Lintern et al., 2018; Chua et al., 2019).

Because of their low-lying position in the landscape, riparian ecosystems are also exposed to the cumulative effects of pressures in their catchments, in both terrestrial and aquatic realms (Capon et al., 2013a,b). Changes to hydrological regimes due to upstream water resources developments, for example, can have dramatic effects on patterns of water availability and flooding in downstream riparian zones with significant implications for ecosystem structure and function (Nilsson and Svedmark, 2002). Changes to land cover and land use in upland areas can also have a substantial influence on the quantity and quality of surface runoff and groundwaters flowing into riparian ecosystems. In highly cleared agricultural and urban catchments, for instance, riparian ecosystems can be subject to much greater, flashier runoff bringing elevated sediment loads and pollutants.

Riparian ecosystems are additionally highly vulnerable to species invasions, especially by exotic plants (Richardson et al., 2007). Low resistance to plant invasion in riparian ecosystems is often attributed to their high levels of intrinsic (e.g., hydrological) and human disturbance, high edge to surface area ratios and the diversity of dispersal vectors available to colonizing plants (Capon and

Pettit, 2018). Changes to hydrological regimes are also widely associated with plant invasions in riparian ecosystems globally (Catford et al., 2011; Merritt and Poff, 2010). In turn, exotic plant invasions can have significant repercussions for ecosystem functions, e.g., the quality of leaf litter entering aquatic food webs.

Multiple direct and indirect pressures affecting riparian ecosystems interact with each other, often resulting in highly deleterious outcomes at both local and catchment scales. Climate change represents a further “umbrella” pressure that can affect the structure and function of riparian ecosystems both directly (e.g., by altering hydrological regimes) and more indirectly through its effects on other threats and pressures and the sensitivity of riparian ecosystems and biota to these. In general, riparian ecosystems are anticipated to be highly vulnerable to climate change impacts because of their high levels of exposure to altered climatic stimuli and disturbances as well as their high levels of sensitivity to these (Capon et al., 2013a,b). While riparian biota and ecosystems might also be expected to have relatively high levels of resilience and adaptive capacity in the face of climate change, having developed under conditions of environmental variability, this is likely to be significantly constrained in many places by the presence of intensive human threats and pressures. The capacity of riparian ecosystems and biota to adaptively respond to altered climatic disturbances such as extreme floods, for instance, is often severely limited due to the presence of hard infrastructure such as bank armouring or levee banks.

Conservation and Management

Historical approaches to managing riparian ecosystems have often tended toward the replacement or enhancement of certain ecosystem services through the construction of hard, engineered infrastructure, e.g., levee banks and bank armouring for flood mitigation. Recent decades, however, have seen growing appreciation of the importance of riparian ecosystem conservation and restoration at both local and catchment scales because of the disproportionate value and critical importance of the ecological functions and services which they support (Seavy et al., 2009; Capon et al., 2013a,b; Capon and Pettit, 2018). Conservation and restoration of riparian ecosystems have a high potential to generate multiple benefits across a range of scales with a relatively low risk of perverse outcomes. Indeed, riparian restoration now represents a multi-billion-dollar industry globally (Bernhardt et al., 2005; Brooks and Lake, 2007; Palmer et al., 2005), although appropriate approaches to this remain a matter for debate.

In general, protecting intact native riparian ecosystems should be prioritized at catchment scales. This can involve incorporation of riparian areas in reserve networks as well as the implementation of management strategies to minimize existing threats and pressures, e.g., limiting vegetation clearing, fencing to exclude grazing, prohibiting physical disturbances, etc. (Capon and Pettit, 2018). Where riparian ecosystems have been modified and degraded, restoration actions may also be necessary to restore ecosystem functions. Such interventions can include passive, open-ended approaches which seek to promote natural regeneration of vegetation by restoring hydrological regimes, removing armouring and dechannelizing watercourses or restoring physical habitat structure, e.g., returning boulders. More active restoration approaches typically involve direct seeding or planting, usually of native, often woody, species.

Control and eradication of exotic plants, by spraying herbicides or mechanical means, represents a particularly widespread focus of riparian restoration efforts globally. The effectiveness of weed control in riparian zones, however, remains poorly understood (Capon and Palmer, 2018). Furthermore, there is increasing evidence that exotic plants have the potential to support some crucial ecological functions and ecosystem services in degraded landscapes, especially under a changing climate and land use intensification (Capon and Palmer, 2018). Some (e.g., Davies, 2010), have further suggested that the increasing pressures of the Anthropocene era, along with the critical importance of riparian ecosystem functions, warrants consideration of over-restoration to enhance specific functions (e.g., shading) by planting targeted species (e.g., fast-growing, high shade species). Overall, such controversies reflect a rising interest in prioritizing conservation, restoration and environmental management actions in riparian landscapes in relation to their capacity to protect and restore critical ecosystem functions (e.g., bank stability, water quality regulation etc.). Rather than attempting to preserve or restore the historic composition and structure of riparian ecosystems, therefore, interventions may be favorable if they promote the spatial (and temporal) heterogeneity and connectivity of riparian landscapes which, in turn, support their capacity to supply so many vital ecosystem services.

Research Needs

Throughout the world, there is a plethora of significant knowledge gaps regarding the basic biology and ecology of riparian biota and ecological processes. Given the urgent need for robust scientific knowledge to inform planning and management of conservation and restoration strategies, however, a priority has emerged to better understand how riparian functions, services and values are underpinned by ecosystem composition and structure (Capon and Pettit, 2018). To design and implement effective and robust management strategies, it is also imperative that we improve our capacity to predict the ecological responses of riparian ecosystems to disturbances and interventions over multiple spatial and temporal scales.

Abstract

Groundwater and associated aquifers are considered essential resources for the maintenance of human life. However, the quality of groundwater and recharge rates has been diminished in many areas of the world. This poses a real threat to the health of aquifers and groundwater-dependent ecosystems such as springs, wetlands, streams, rivers, and lakes and the economies they support. Hydrological recharge of aquifers is complex and is affected by climate, geology, soil type, vegetation, and land use. Managers are becoming increasingly aware that aquifers are dynamic ecosystems rather than just water stored underground and that we need to identify and manage for the environmental values associated with groundwater. Sustainable groundwater management will allow groundwater to be maintained for an indefinite time without having unacceptable environmental, economic, or social consequences.

Introduction

Groundwater is the most important freshwater resource on earth (Bakker and Anderson, 2011). Water may be found in the ground almost everywhere but emphasis is usually placed on areas which contain and conduct substantial amounts of water groundwater (Bachmat, 2005). These areas are usually found in geological formations of permeable rock or loose material and are referred to as "aquifers." Aquifers of particular interest are those in which the water is renewable, in contrast to aquifers which contain fossil groundwater, a one-time, nonrenewable resource. It is a substantial resource making up approximately 37% of the Earth's non-ocean water, compared to 63% for ice and less than one half percent for surface water (e.g. rivers, lakes) (Trenberth et al., 2007; Beckie, 2013). More than two billion people world-wide rely on groundwater for their daily supply of drinking water (Griebler and Avramov, 2014).

A number of groundwater-dependent ecosystems rely on aquifers to maintain their composition, structure, and function (Kløve et al., 2011). Groundwater makes an essential contribution to other aquatic ecosystems including river, lakes, wetlands, and springs (Boulton, 2005). The aquifer itself is also an important ecosystem (Humphreys, 2006). In fact, aquifers are dynamic systems comparable in complexity to surface ecosystems (Tomlinson and Boulton, 2010). Groundwater is also an important source of water for public water supply, agriculture, and industry (Barlow and Leake, 2012; Sankarasubramanian et al., 2017; Seo et al., 2018). In the United States, groundwater supplies 25% of the fresh water used for all purposes; approximately 50% of the population relies on groundwater as its primary source of water for drinking (Zektser and Everett, 2004; Bachmat, 2005). The use of groundwater in the United States is increasing more rapidly than the use of surface water.

This increasing demand for groundwater resources has resulted in the need for better groundwater management (Danielopol et al., 2003; Humphreys, 2006). Managers are becoming increasingly aware that aquifers are dynamic ecosystems rather than just water stored underground and that we need to identify and manage for the environmental values associated with groundwater. The occurrence of little-known groundwater species delayed mining in Western Australia because of concerns the species would become extinct (Schmidt and Hahn, 2012). Groundwater ecological surveys are now required there by government legislation for developments that may impact aquifers (Tomlinson and Boulton, 2010; Stein et al., 2010).

Hydrologic and Geomorphologic Characteristics

Groundwater moves along established flow paths from recharge areas to discharge areas within springs, streams, lakes, and wetlands (Kløve et al., 2011). Recharge of the saturated part of the aquifer occurs whenever water from precipitation enters the ground. Actual

recharge pattern will vary locally depending on hydroperiod (defined as the duration of inundation in a year (Crase et al., 2013)) which is affected by water use, slope, topography, climate, and geology. Alfaro and Wallace (1994) described four types of hydroperiod: (1) periodic—A clear seasonal pattern dependent on precipitation and evapotranspiration, (2) intermittent—A large variability in flow patterns, (3) episodic—An irregular flow that occurs only when water levels are high, and (4) perennial—A continuous and consistent source year round.

Biological Characteristics

The environment in which aquifer ecosystems develop is characterized by darkness, consistency and persistence of habitat, and low energy and oxygen availability (Dresel et al., 2010). Most groundwater systems are characterized by low exchange (Humphreys, 2009) and low, if any, autotrophy (i.e., self-sustained production of organic matter from inorganic substances) (Schmidt and Hahn, 2012). As such, they have been traditionally considered as biological deserts (Gibert et al., 1994). Recent studies have shown that groundwater systems support a great variety of organisms (Deharveng et al., 2009), which provide important ecosystem services including water purification, bioremediation, water infiltration, and water transport (Boulton et al., 2008).

Groundwater carries a continuous flux of dissolved ions, nutrients, and organic matter that make an important contribution to linking the biological diversity of groundwater, surface water, and terrestrial ecosystems (Boulton, 2005; Barquin and Scarsbrook, 2008; Kløve et al., 2011). Lack of light in groundwater systems limits producers and grazers but dissolved organic matter and other nutrients support a food web of detritivores (Boulton, 2005). Groundwater systems often show gradients in organic carbon, oxygen, salinity, pH, and water chemistry along the groundwater flow path and with depth within the aquifer (Humphreys, 2006). Groundwater ecosystems are typically low in sources of energy (Huppopp, 2000; Humphreys, 2006). Subterranean biota usually rely on energy from particles of organic matter that was derived from surface plants and transported to subterranean habitats by water flow, percolation, or gravity (Deharveng and Bedos, 2000).

Animal Communities

Groundwater ecosystems support organisms from microbes such as bacteria to macro faunal crustaceans (Reiss et al., 2019). Many species are endemic to this ecosystem and are adapted to the low energy levels and lack of light (Griebler and Lueders, 2009; Marmonier et al., 1993). The organisms that inhabit these environments are often specialized morphologically and physiologically (Dresel et al., 2010). They are also predominantly invertebrates. These stable and confined environments result in high levels of endemism and high proportions of relict species in comparison to surface environments (Danielopol, 1989). Stygobites are obligate inhabitants of groundwater systems (Humphreys, 2006) and are generally crustaceans, but may include worms, snails, mites, insects, and fish (Humphreys, 2000, 2002; Humphreys and Harvey, 2001).

Commercial Uses

Aquifers can be used for storing surplus amounts of water (Bachmat, 2005). Subsurface storage of water saves losses of land and water lost through evaporation which occur with storage of water in surface reservoirs.

Among the many other services that groundwater ecosystems provide to humans (Boulton, 2009), the most valuable are drinking water supply (Van der Gun, 2012) and water used for irrigation for both traditional and intensive agricultures (Burke, 2003). Nearly all of the irrigation water in the United States is drawn from groundwater (Kenny et al., 2009). Consequently, groundwater extraction for irrigation in the high plains of the United States has depleted aquifer systems (Wada et al., 2010).

Habitat Change

The wellbeing of groundwater invertebrate communities increases with increasing associated surface area occupied by riparian forests and decreases under intensified agriculture use (Español et al., 2017). Also, key ecosystem services increased twofold with increasing area of forest. This is likely due to high concentrations of nitrates and sulfates associated with agriculture systems that affect the diversity of groundwater invertebrate communities.

An increasing human population results in an increasing demand for groundwater. As a result, groundwater resources are often being depleting faster than they can be replenished (Gleeson et al., 2012). Continued extraction of groundwater resources often leads to depletion of water in springs and wetlands and flows of streams and rivers since groundwater and surface water are a tightly coupled interconnected system (Mueller and Male, 1993; Winter et al., 1998; Sophocleous, 2002; Kumar et al., 2009).

Invasive Species

Invasive plant species can consume large amounts of groundwater, causing down-stream springs and wells to dry up (Calder and Dye, 2001; van Wilgen et al., 2008). However, limited work has been done on the effects of invasive plants on groundwater resources (Gorgens and Van Wilgen, 2004). The economy in arid regions of South Africa relies heavily on access to groundwater; many of these areas are also being invaded by mesquite (*Prosopis* species). Water use by these invaders is estimated to exceed 134 million m³ annually (Le Maitre, 2001). This could have a significant impact on the ability of these groundwater resources to continue to meet human demands (Gorgens and Van Wilgen, 2004).

Also, estimates of potential expected losses from an invasion of *Miconia calvescens* on Oahu, Hawaii, United States to groundwater recharge may be as high as \$137 million (USD) per year (Kaiser and Roumasset, 2002). Programs established to reduce the surface cover of alien invasive plant species and replacing these with native vegetation have reduced evapotranspiration and have contributed to recharge of shallow aquifers (Hayward, 2005).

Pollution

Contamination of groundwater occurs from point and nonpoint sources. Anthropogenic point sources include solid-waste dumps and landfills, mine-tailings, septic tanks, cesspools, injection wells of inferior-quality water, and aboveground and underground storage tanks of hazardous and nonhazardous waste materials (Bachmat, 2005). Anthropogenic nonpoint sources include application of agricultural chemicals, irrigation with poor-quality water, percolation of atmospheric pollutants, and urban runoff. Point sources are more easily identified than nonpoint sources and can be better managed and mitigated. Nonpoint sources tend to result in large-scale effects that are difficult to monitor and manage (Bachmat, 2005).

Once pollutants have reached the water table, their spread throughout the groundwater system is slow because water movement is generally very slow (Alley, 2009). Consequently, once contaminants have reached an aquifer, the time required for water quality to recover as a result of natural processes will likely be long after the sources of contamination have been removed. As a result, restoration of water quality in aquifers is generally very expensive and often only partly successful.

Climate Change

Climate change may be responsible for approximately 20% of projected world-wide increases in scarcity of water (Sophocleous, 2004). The challenges of understanding the effects of climate change on groundwater and aquifers are unique because climate change may affect hydrogeological processes and groundwater resources directly and indirectly, in ways that have not been fully realized (Dettinger and Earman, 2007; Green et al., 2011).

Extreme rainfall events resulting from the effects of climate change are expected to become increasingly more frequent in the northern hemisphere (Min et al., 2011; Taylor et al., 2013). Apart from the devastating impact on the economy and human livelihoods (Munro et al., 2017), flooding has the potential to detrimentally impact freshwater ecosystems, including groundwater and aquifers (Taylor et al., 2013; Reiss et al., 2019). During such extreme rainfall events, infiltrating water can potentially transport pollutants and nutrients, including carbon, from the surface to the aquifer (Taylor et al., 2013; Reiss et al., 2019), affecting groundwater ecosystems.

Others are anticipating that climate change will pose additional major threats to groundwater resources in the near future. Sandstrom (1995) suggested that a 15% reduction in precipitation, with no change in temperature, resulted in a 40–50% reduction in recharge of groundwater. Increased variability in precipitation, temperature, and evapotranspiration will thus significantly affect groundwater recharge and accessibility (Treidel et al., 2012). Riedel (2019) reported that aspects of groundwater quality change due to warming which may, in turn, increase the costs for purification when drinking water is produced from groundwater resources and may also result in some aquifers becoming uninhabitable for groundwater biota.

Further, the lowering of the groundwater table due to changes in precipitation patterns and rises in temperature may reduce irrigation well yield and increase pumping cost, which may seriously affect the livelihood of farmers in the regions where groundwater is used as the major source of irrigation (Salem et al., 2017). Mitigation of the impacts of climate change on groundwater resources to address increasing costs associated with irrigation and to maintain farmers' profits is likely to be a major challenge, particularly in developing countries whose economy is based on agriculture (Salem et al., 2018).

Conservation and Management

Subterranean sites present special conservation and protection problems (Culver and Pipan, 2013). Since they are out of sight, they are often overlooked during land management planning even though the groundwater–surface-water interface may be significantly degraded as a consequence of human activities (Bencala, 2011). Also, at the aquifer scale, a significant link between abundances, species richness, and composition of stygobite assemblages and human activities has been established (Marmonier et al., 2018). Groundwater is threatened by land-use practices, pollution, and extensive water use for irrigation (Kløve et al., 2011). Deforestation

and draining of wetlands can expedite surface runoff and reduce ground water recharge (Alley, 2009). Some agricultural tillage systems, impoundment of streams, and development of artificial wetlands can increase ground water recharge. Urbanization may either increase or decrease recharge. Protection of groundwater environments, and the species they support, requires protection from both excessive draw down and contamination of the aquifer (Culver and Pipan, 2013). This, in turn, requires greater public awareness and appreciation of groundwater environments.

Management measures to protect groundwater ecosystems should include the conservation, creation, and expansion of riparian forest corridors, especially in floodplains supporting intensive agriculture (Español et al., 2017). Also, reduction and careful application of agricultural fertilization and pesticides are needed to reduce contamination of groundwater and aquifer resources. Sustainable groundwater management will allow groundwater to be maintained for an indefinite time without having unacceptable environmental, economic, or social consequences (Alley et al., 1999).

Conclusions

"Ground water and surface water: A single resource." The recognition of this relationship has been established through the results of numerous field studies demonstrating the ongoing connections between groundwater aquifers and springs, wetlands, streams, rivers, and lakes (Bencala, 2011). However, groundwater and aquifers continue to be, for the most part, an unexplored aquatic ecosystem (Boulton et al., 2008). Their contribution to biological diversity and ecosystem services are generally undervalued, making their effective protection and wise management difficult. However, environmental policy and, in particular, European water legislation, in the framework of the EU Groundwater Directive, has started to consider groundwater not only as a resource but as a living ecosystem (Reichert, 2019).

Although there is a growing awareness of the complexity of groundwater ecosystems, increasing demands for water extraction and the associated declining availability and quality continue to generate threats (Millennium Ecosystem Assessment, 2005). Reliable evaluations of groundwater and aquifer ecosystem health are essential for the development and implementation of successful management and restoration strategies (Boulton, 2005; Griebler et al., 2014). Given the increasing threats and the general inaccessibility of groundwater environments, it is important to bring new conceptual designs and techniques to the field (e.g., Saccò et al., 2019). This will help to better inform management decisions affecting these ecosystems which are under pressure from climate change, overexploitation, and degradation.

Abstract

Glaciers and ice sheets are masses of ice and snow that persist over many years formed by the accumulation and compaction of snow. They cover a significant amount of the Earth's land surface and store most of the world's fresh water. Glaciers flow under their own weight, carving out landscapes and transporting sediment and rocks as they move, and they advance and retreat in response to changes in the mass balance, or difference between annual accumulation and ablation. Glaciers and glacierized river basins have unique hydrological characteristics. They serve as an important store of freshwater and influence the characteristics of annual and seasonal runoff downstream. Glaciers and ice sheets also represent an important biome with a rich diversity of life, from microbial communities to microscopic organisms and macroinvertebrates, and they influence ecosystem functioning well beyond their margins and termini. In recent decades, most glaciers worldwide have been losing mass and retreating in response to climatic variations, now primarily driven by human activity. The Greenland and Antarctic Ice Sheets have also begun to lose significant amount of mass and have exhibited an accelerating pattern of loss. This is expected to continue for many decades or more under current and expected future climate conditions, with the loss of much of the world's mountain glaciers, and significant changes in polar ice caps and ice sheets. The loss of glaciers and ice sheets poses many problems and challenges, including sea level rise implications, regional changes in water availability, impacts on glacial and downstream ecosystems, release of legacy contaminants stored on and within glaciers, glacier-related hazards, feedback effects on regional and global climate, and many others that affect the wellbeing of people and communities. There is a need for more observations, better understanding and prediction of glacier dynamics, coordinated adaptation and mitigation strategies across multiple levels from local to international, and a coupled systems approach that integrates physical dimensions of changing ice environments with the human systems that engage with or depend upon them.

Global Distribution and Physical Characteristics of Glaciers

Glaciers are masses of ice and snow that persist over multiple years and undergo deformation and flow under their own weight and the influence of gravity. They range in size and form, from the smallest mountain cirque and niche glaciers ($\sim 10^3$ – 10^0 km²) to the vast polar ice caps and the continental ice sheets of Greenland and Antarctica (10^4 – 10^6 km²), covering about 10% of the Earth's land surface and storing over 33 million km³ of freshwater (Benn and Evans, 1998). Glaciers form through the accumulation of multiple layers of snow, and are thus restricted to very cold regions and/or areas with heavy snowfall, such as high latitudes and high elevation mountainous regions. Aside from the Greenland and Antarctic Ice Sheets (1.7×10^6 and 14×10^6 km², respectively), there are roughly 216,000 glaciers worldwide. These cover an area of almost 706,000 km² (RGI Consortium, 2017; Fig. 1; Table 1), mostly in the Arctic and Antarctic polar regions, the mountainous regions of Alaska and western North America, southern and central Asia, the European Alps, and the South American Andes. The vast majority of the world's tropical glaciers are found in the Andes at elevations above 4000–5000 m, with the largest number in the Peruvian Andes (Schoolmeester et al., 2018). The recently updated Randolph Glacier Inventory (RGI) is a complete global inventory of glacier outlines, and provides information on their hypsometry (area–elevation distribution) for the different regions shown in Fig. 1 and for individual glaciers, as well as information on characteristics such as the surface slope, aspect, length, and other variables of each glacier (RGI Consortium, 2017).

Glacier ice is formed by the metamorphism and compaction of snow, a process that can take from several years to decades, or even centuries or more, depending on the temperature, occurrence and frequency of melt, and other factors (Patterson, 1994). Fresh snow (with a density of 50–200 kg m^{−3}) transforms into *firn* (400–830 kg m^{−3}) after it has lasted through a melt season and undergone significant change in crystal morphology and structure. As further compaction occurs under the growing weight of accumulating snow, ice crystals become larger, the pore volume decreases and air passages become smaller and more isolated, the *firn* transforms into dense glacial ice (830–910 kg m^{−3}) with a deep blue hue. In very cold environments with low snowfall rates, such as the polar regions, this process occurs very slowly and over depths of many tens of meters. Conversely, where snowfall rates

From the Randolph Glacier Inventory version 6.0 (RGI Consortium (2017) Randolph glacier inventory—A dataset of global glacier outlines: Version 6.0: Technical Report, Global Land Ice Measurements from Space, Colorado, USA: Digital Media. <https://doi.org/10.7265/N5-RGI-60>).

are higher and melting occurs more frequently, such as in more temperate mountain environments, the process can be completed within a few years and at depths of several meters (Benn and Evans, 1998).

Snow accumulation and ablation rates vary over the surface of a glacier due to variations in air temperature, snowfall amount, net radiation, wind, and other factors. In steep and complex mountain terrain, processes such as avalanching and wind redistribution from surrounding slopes can significantly enhance the local accumulation over parts of the glacier surface. The upper portion of a glacier, where snowfall amounts are generally higher and air temperatures are cooler, is referred to as the accumulation zone. It is defined where annual net accumulation exceeds annual net ablation (i.e., melting and sublimation). The lower portion is referred to as the ablation zone (where net annual ablation exceeds net annual accumulation). These zones are separated by a line, along which annual accumulation and ablation are in balance, referred to as the equilibrium line. This generally coincides with the end-of-summer snowline. Fig. 2 shows an idealized schematic of these features. Averaged over the entire surface, the difference between the annual gains and losses of snow and ice is referred to as the glacier's annual net mass balance, which can be partitioned into winter and summer components, and is measured using various in situ, remote sensing, or proxy methods (Hubbard and Glasser, 2005; Cogley, 2017).

On some glaciers, the pattern of mass gains and losses is more complex than this idealized model. Where glaciers and ice sheets terminate in large water bodies (such as proglacial lakes, fjords, or the open ocean), a significant portion (or all) of the mass loss may occur through the calving of ice. A considerable amount of melt occurs on the underside of floating ice shelves and where ice is in contact with water bodies. *Dry calving* may also occur from smaller cirque and hanging glaciers in steep mountain areas, where masses of ice, or *seracs*, break away from glaciers and move downslope to eventually melt far below or accumulate on other ice masses. Debris-covered glaciers, which are characterized by a continuous and thick layer of rocks, sediment, and other material (from 0.03 m to as much as 2 m), are common in steep and erodible mountains, and the melt characteristics of such glaciers are highly complex due to the insulating properties of the debris (Kirkbride, 2011).

Under steady state conditions, net annual mass balance fluctuates around zero and any annual excess ice mass is transferred from the accumulation to the ablation zone by ice flow to maintain the glacier's longitudinal topographic profile (Fig. 2). This flow occurs by plastic deformation in cold-based glaciers that are frozen to the underlying substrate, but may also involve sliding at the ice–substrate interface and deformation of subglacial sediment and till in warm-based glaciers (i.e., where ice is at the pressure melting point at the glacier bed and liquid water is present at the base of the glacier) (Patterson, 1994). Rates of flow can vary tremendously, from very slow, cold-based glaciers with low accumulation rates (maximum velocities approximately several meters per year), to warm-based glaciers with high accumulation rates and/or topographic surroundings that funnel ice into ice narrow streams (with maximum velocities of over 8000 m yr⁻¹) (Benn and Evans, 1998). For most temperate glaciers, however, typical velocities are of the order of a few tens to hundreds of meters per year. This flow creates a variety of distinctive features, most notably crevasses, fractures in the glacier surface, which form due to tensile or shear stresses in the ice that are linked to velocity variations across the surface and at the margins of the glacier, and can be up to hundreds of meters in depth (Colgan et al., 2016).

Changes in climate that perturb glacier mass balance over long periods cause an adjustment in glacier form and flow toward a new equilibrium condition. This leads to progressive changes in glacier geometry, flow velocity, surface elevation, and terminus position, with the magnitude and timing of the response depending on factors such as the degree of change in mass balance, the size, shape, slope, velocity, and hypsometry of the glacier, and other morphological factors (Patterson, 1994). Changes in climate can also affect other properties, such as the ice temperature and deformation rate, the presence and distribution of meltwater at the glacier bed, and the interactions between glaciers and surrounding terrain and water bodies. In general, the characteristic response time for a temperate valley glacier to adjust is on the order of several decades (Raper and Braithwaite, 2009). Thus, at regional scales, the collective behavior of a region's glaciers can provide a useful indication of recent and contemporary climatic trends and variability. Other glaciers, such as ice caps in polar regions, can have response times on the order of centuries (Burgess and Sharp, 2004), while the large continental ice sheets adjust over periods of millennia or longer. However, they are also capable of rapid dynamic ice-marginal changes, as has been observed recently in Greenland and Antarctica, and are potentially subject to dynamic instabilities where they are grounded below sea level (Alley et al., 2005; Schoof, 2007; Hock et al., 2017; Fig. 2).

In regards to its influence on the land surface, the flow of glacial ice is one of the most significant geomorphic agents on Earth, eroding, transporting, and depositing rocks and sediment and shaping a wide variety of distinctive landforms and landscapes (Menzies, 2002, 2018). Over many centuries and millennia, the advance and retreat of glaciers and ice sheets has shaped the surface topography and geology of much of North America, Eurasia, and many of the world's mountain regions (Benn and Evans, 1998). The reader is referred to these other texts for a full description of the various glacier landforms and geomorphic processes.

Past and Future Glacier Changes

Throughout Earth's recent history, glaciers have advanced and receded in response to paleo-climatic variations, primarily as a result of well-understood cycles in the Earth's orbit and rotation (Solomina et al., 2015). At times in the Quaternary Period, referred to as glacial periods, up to one third of the Earth's land surface was covered by ice and global sea levels were over 100 m lower than at present (Alley et al., 2005; Cronin, 2012). During the height of the last glacial maximum (ca. 20,000 years ago) much of northern North America and significant parts of northern Europe and Asia were covered by the Laurentide and Feno-Scandian Ice Sheets, which were vast in size and up to several kilometers thick (Benn and Evans, 1998). Rapid retreat of these ice sheets began several thousand years after this, as a response to warmer climate conditions that marked the beginning of the present interglacial period,

Fig. 2 Idealized schematic diagram of glacier form and flow, noting some of the characteristic features and describing some of the changes taking place for a) mountain glaciers, and b) polar ice caps and ice sheets. Not to scale.

but it took many thousands of years for them to disappear, leaving the present day glaciers and ice sheets as vestigial remnants of this former ice cover. There have been short-lived periods of glacier advance during the Holocene, the most recent and well-documented of which is the *Little Ice Age* (LIA), which occurred across the globe from about the 16th to the early 20th century and resulted in the advance of many glaciers by distances of up to several kilometers (Benn and Evans, 1998).

Since the end of the LIA, most glaciers worldwide have been losing mass and retreating. Clearly visible moraines and trimlines provide evidence of the recent maximum extents of these glaciers (Bolch, 2017; Paul and Bolch, 2019; Figs. 2 and 3), and photographic and anecdotal evidence documents their retreat. There have been some instances of glacier stability or even advance, for both individual glaciers and groups of glaciers. Surge-type glaciers, though uncommon, exhibit periodic sudden changes in flow rate and may advance in periods of rapid flow and then stagnate or retreat during slow phases of the surge cycle. However, recent changes in glacier extents have generally not approached the maximum positions reached in the LIA (Solomina et al., 2015).

Fig. 3 Little Ice Age moraines indicating the extent of former glaciation in (A) the Purcell Mountains of British Columbia, Canada, and (B) the Khumbu Mahalangur region of the Himalayas, Nepal. Photos: Chris DeBeer.

Remote sensing and in situ observations over the past several decades show a clear and coherent pattern of negative mass balances, glacier thinning and area loss, and terminal retreat, although there have been regional and inter-annual variations (Gardner et al., 2013; Vaughan et al., 2013; Zemp et al., 2015; DeBeer et al., 2016; Medwedeff and Roe, 2017; Schoolmeester et al., 2018; Bolch et al., 2019; Wouters et al., 2019; Hock et al., 2019). The rates of glacier shrinkage and mass loss have been accelerating over the past few decades (Zemp et al., 2019), and the proportion of the observed mass loss that is attributable to anthropogenic climate warming has increased dramatically, such that this is now the dominant driver of global glacier changes (Marshall, 2014; Marzeion et al., 2014a,b). Summer melt rates have increased greatly over the Greenland Ice Sheet and other Arctic ice caps, and melting of ice shelves in West Antarctica by warm ocean water has driven acceleration, thinning, and retreat of major outlet glaciers (Sharp et al., 2011; Meredith et al., 2019; Fig. 2). The current rates of glacier mass loss are unprecedented for the period of observations, and probably also for the Holocene (Zemp et al., 2015; Solomina et al., 2015). The recently released IPCC Special Report on The Ocean and Cryosphere in a Changing Climate (IPCC, 2019) provides an authoritative and comprehensive summary of these changes within both mountain and polar regions.

It is challenging to quantify glacier mass loss at regional and global scales due to the sparsity of direct measurements together with limitations of remotely sensed data such as the relatively short time period of observations, coarse resolution of gravity-based measurements from NASA's GRACE (Gravity Recovery and Climate Experiment; (https://www.nasa.gov/mission_pages/Grace/index.html), and other problems in deriving digital elevation models from optical and altimetric observations. Nevertheless there have been numerous recent studies using a variety of approaches to quantify trends in land ice mass and its contribution to sea level rise (e.g., Bamber et al., 2018). Based on in situ mass balance observations, the average cumulative mass balance of a set of 41 globally distributed reference glaciers indicates a collective loss of 23 m water equivalent over the glacier surfaces between 1960 and 2018 (WGMS, 2018; C3S, 2019) but with considerable variability among individual glaciers and regions. By extrapolating glaciological and geodetic observations, Zemp et al. (2019) found that glaciers distinct from the Greenland and Antarctic Ice Sheets contributed 27 ± 22 mm to global mean sea-level rise from 1961 to 2016, with approximately one third of this originating from Alaska. Although the potential contribution to sea level rise of mountain and polar glaciers is relatively small compared to that of the two major ice sheets (i.e., 0.3 m cf. 70 m, respectively; Alley et al., 2005; Farinotti et al., 2019), these glaciers have lost significant mass and they were the dominant contributor to sea level rise during the 20th century (Vaughan et al., 2013). Table 2 provides estimates of the sea level contribution from glacier mass loss in recent decades. In addition to the steadily rising contribution from mountain and polar glaciers, the contributions from the ice sheets have increased rapidly to become the dominant source of mass input to the oceans.

The future responses of glaciers to climate warming is of great scientific interest and societal importance. Already, anecdotal evidence is showing that many mountain glaciers are losing substantial mass due to melt under extremely warm summer conditions, and even higher winter snowfall is insufficient to compensate for the effects of heat waves and intense melting conditions in summer (e.g., see the news article by Harvey, 2019). Given their present configuration, most temperate glaciers are out of balance with current climate and will continue to recede to adjust their geometry to current conditions (Huss et al., 2017; Marzeion et al., 2018). Ongoing climate warming is expected to further exacerbate the current mass imbalance, leading to rapid and pronounced deglaciation over the remainder of this century. Model projections for mountain and polar glaciers indicate that they will lose from 25 to 48% of their current volume by the late-21st century, with sea level contributions that could range from 50 to 170 mm (Huss and Hock, 2015; Marzeion et al., 2018). For some regions, such as western Canada, projections show even greater relative losses of up to 90% or more by that time (Clarke et al., 2015). 21st century mass losses from the ice sheets could be potentially much more significant, contributing from 0.5 m to as much as 2 m or more to sea level rise by 2100 (Oppenheimer and Alley, 2016; Oppenheimer et al., 2019; Meredith et al., 2019). The future response of the ice sheets to ongoing climate warming remains very uncertain (see Section “Challenges and Priorities”).

Table 2 Contribution of glaciers and ice sheets to rates of global sea level rise for various recent time periods.

Source	Contribution rate (mm yr ⁻¹)			
	1961–2016	1992–2001	2002–2011	2012–2016
Mountain and polar glaciers ^a	0.48 ± 0.39	0.37 ± 0.12	0.52 ± 0.09	0.63 ± 0.08

Hydrological Characteristics and Importance

Glacial ice is an important store of freshwater that can significantly influence regional hydrological cycling, depending on the extent of glaciation in a river basin, and plays a major role in the global hydrological cycle (Jansson et al., 2003). Nearly 80% of the world's freshwater is stored in glaciers and ice sheets, with about 99% of this contained within the Antarctic and Greenland Ice Sheets and the remainder in mountain and polar glaciers worldwide (Vaughan et al., 2013; IPCC, 2019). Globally, the melting and loss of glaciers has major implications for sea level rise (see previous section), while regionally, glaciers provide seasonal runoff contributions to downstream river systems that can sustain discharge in summer after the melt of most of the seasonal snow cover. Glacier melting can also provide a buffering mechanism to help sustain discharge during unusually warm and dry periods. At the global level, 370 (140) million people live in river basins where glacially derived meltwater contributes at least 10% (25%) of river discharge on a seasonal basis (Schaner et al., 2012), but in many regions the relative contribution is much higher than this, especially in drought years.

Meltwater generation, the seasonal evolution of the glacier drainage system, and runoff are complex processes and highly dynamic over space and time, involving surface, englacial, and subglacial components (Nienow and Hubbard, 2005; Sharp, 2005; Irvine-Fynn and Hubbard, 2017). The hydrology of glaciers is closely tied to their dynamics and flow behavior, as water availability and drainage characteristics at the base of glaciers influence friction and sliding (Flowers and Clarke, 2002a,b; Anderson et al., 2004; Sharp and Tranter, 2017). Water enters the system from melting ice and snow, rainfall, and runoff from ice-free areas, and is stored throughout the glacier system in the snowpack, firn, supraglacial and ice-marginal lakes, englacial water pockets, subglacial cavities or lakes, and subglacial sediments (Fig. 2). Meltwater is predominantly generated at the surface and its runoff exhibits a distinct diurnal signal, but melt can also occur internally within the glacier and at the glacier bed if ice is at the pressure melting point (Patterson, 1994). Early in the melt season, water is transferred from storage in snow and firn and begins to flow across the glacier surface and into the glacier drainage system as it develops in response to the seasonal increase in meltwater fluxes. Early season runoff is slow and inefficient as flow through snow is attenuated and delayed, and the internal network of drainage channels and conduits has mostly closed down during the winter. With continuing melt and depletion of the snowpack, drainage reorganization occurs as runoff production increases, the channel and conduit network opens and expands, active drainage pathways connect to various storage sites on and within the glacier, and water is conveyed more rapidly and efficiently through the system. At the end of the melt season when water production and flow through the glacier decline, the drainage system begins to close as rates of ice deformation into now largely empty englacial channels increases.

The evolution and form of the drainage system is strongly controlled by the structure and temperature of the glacier ice. At the surface, water production is spatially distributed and runoff is focused by topography, forming a network of channels, ponds, and small lakes (Fig. 2). Crevasses and moulins intercept surface flow pathways, rapidly conveying water into the englacial system. The distribution of crevasses therefore controls the surface drainage density and the routing of supraglacial meltwater (Nienow and Hubbard, 2005; Colgan et al., 2016). Where the surface ice layer is cold, streams tend to flow for greater distances before entering the glacier or reaching its margins (Nienow and Hubbard, 2005). In some cases surface melt draining down into surface snow and firn may refreeze, forming thick ice layers. These ice layers may cause percolating water to pond above them, to the point that the snow becomes water saturated and starts to move downslope as slush flows and slush avalanches that can travel significant distances from their point of initiation. These slush flows may carve out surface channels that are subsequently occupied by seasonal meltwater streams.

Drainage through the glacier interior can occur through micro-scale channel networks and interstitial flow paths, but the bulk of the water flows through larger conduits and ice fractures, moving quickly toward the glacier bed and terminus. At the glacier bed, drainage occurs via both distributed (slow) and channelized (fast) systems (Sharp, 2005). Distributed systems involve thin films, linked cavities, and flow through sediment pore space and fracture systems. Channelized systems involve flow through ice-walled conduits (Röthlisberger or R-channels) that are kept open where the rate of wall melting exceeds the rate of conduit closure due to ice creep, or through channels incised into the underlying bedrock (Nye or N-Channels) or subglacial sediments. Distributed subglacial drainage systems often involve sections of channel incised into bedrock that act to link together larger cavities that form in the lee of bumps on the glacier bed and may become water-filled during the melt season. These distributed subglacial drainage systems may cover large areas of the glacier bed but are generally considered to be less efficient at transmitting water than channelized systems (which they may eventually connect to). Where channels are incised into subglacial sediments, deformation of those sediments in response to the shear stresses imposed on them by the overlying ice may result in deformable sediment periodically blocking the drainage systems, such that water spreads more widely across the bed than usual, and this may have feedback effects on water pressures at the ice-bed interface and on the rate of glacier flow.

Glacierized river basins have distinctive hydrological regimes with discharge characteristics that vary over a range of timescales (Willis, 2005). Seasonally, runoff is concentrated in the melt period, dominated by snow and ice melt, and at times rainfall-generated flows. At other times of the year, runoff is usually comprised of baseflow that is released from slowly draining reservoirs along with groundwater discharge. Basins with relatively high fractions of glacier coverage generally have lower inter-annual variability in runoff than in precipitation, due to the storage and release of water into and from glaciers (van Tiel et al., 2019). At synoptic timescales, meteorological conditions and the nature of the glacier surface control melt rates and runoff generation, which peak when there are high energy inputs to a low albedo surface (e.g., bare ice or dirty/algae-covered ice and snow; see next section). Summer snowfalls tend to raise the surface albedo and suppress melt. Runoff responses vary with the depth of snowpack

and the state of the glacier meltwater drainage system, becoming more rapid and pronounced later in the melt season when the system is well-developed. At daily timescales, melt and runoff vary in response to diurnal patterns of air temperature and radiation receipt, and the meltwater hydrograph is superimposed on a slowly-varying baseflow discharge. As the melt season progresses, the diurnal peak gets larger and more asymmetric, and the time of peak moves forward, reflecting changes in storage, flow pathways, and routing.

Over longer, decadal to century timescales, glacier runoff varies as a result of changes in the volume and area of ice in a river basin. In the current context of climate warming and global glacier loss, there are two competing effects: (1) warmer temperatures increasing the energy available for melt and increasing runoff for a fixed glacier geometry; and (2) negative mass balance causing glacier retreat, especially at lower elevations, reducing the ice-covered source area for melt and eventually glacier runoff volume. Thus, as glacier loss progresses, meltwater contributions to discharge will increase toward *peak water* (Huss and Hock, 2018; Hock et al., 2019)—or more specifically, peak glacier water, which is surplus runoff due to the release from long-term storage—followed by a decline in glacier runoff, even with further warming. Huss and Hock (2018) show that for many mountain regions globally, peak glacier water has already passed or will be approached in the coming several decades. For a few regions with very extensive and/or high elevation ice-cover, mainly in Alaska, the southern Andes, and the high mountains of central Asia, this is expected to occur in the more distant future (i.e., 50–70 years from now).

The loss of glaciers also impacts the variations in river flows, which can be important within the context of the timing of water demands and the need to meet basic domestic needs (generally taken to be 20 L per capita per day). For example, agricultural demands are highest in spring, but require regular water inputs throughout the growing season. Dams are optimized for historical peak flows and energy generation potential. Changes in timing and volume of flows may threaten the ability to meet these water requirements, or pose risks from high flows where glacier runoff contributions are still increasing. It is important to note, however, that river basin discharge and its interannual and seasonal variation depend strongly on this and other components of the hydrological cycle. Changes in precipitation and snow regimes, groundwater storage and cycling, vegetation characteristics, and evapotranspiration processes, which are themselves highly sensitive to climate change, may confound or subsume hydrological responses due to glacier loss alone (e.g., DeBeer et al., 2016). Some recent work has examined glacier change in context with changes in water storage and basin discharge, and found that groundwater can provide a limited and temporary buffering mechanism (Castellazzi et al., 2019; Somers et al., 2019).

Where glacial melt water forms supraglacial, subglacial, and ice-marginal lakes in mountain areas, glacier lake outburst floods, or *Jökulhlaups*, can pose a major hazard from the rapid release of large volumes of water (Roberts, 2005). These floods can be devastating for downstream communities, destroying houses and infrastructure and taking lives. Retreating glaciers have led to the formation and/or expansion of such lakes in many regions worldwide, and this is expected to continue in the coming decades (Hock et al., 2019). As these lakes develop in locations along mountain walls that are susceptible to landslides or where rapid ice disintegration and collapse might trigger outburst floods, there is concern about increasing flood hazard risks, particularly in the high and steep mountains of some developing countries (Schoolmeester et al., 2018; Bolch et al., 2019; Vaidya et al., 2019).

Ecological Characteristics and Importance

Despite extreme habitat conditions, low nutrient availability, and their mostly frozen state, glacier systems are biologically active ecosystems that host a diverse array of life and play an important role in the biogeochemical cycling of elements such as carbon and nitrogen (Barker et al., 2006; Hodson et al., 2008; Anesio et al., 2009; Sharp and Tranter, 2017). The ecology of glaciers is dominated by microbial communities that are adapted to low temperatures, comprised mainly of algae, bacteria, fungi, viruses, and protozoa (Anesio and Laybourn-Parry, 2012; Anesio et al., 2017; Hotaling et al., 2017a,b). Since the presence of liquid water is essential to sustaining microbial processes, habitat for these organisms is restricted primarily to where melting occurs and where water exists. Habitats include wet snow, bare ice surfaces, cryoconite holes (small, localized meltwater-filled holes on the glacier surface harboring bacteria, algae, and fungi; Fig. 4), and streams, ponds, and lakes throughout the glacier system. Micro-organisms have also been found in glacier ice, and sediment rich “basal ice” at glacier beds (Sharp et al., 1999), and as microbial biofilms on the walls of englacial meltwater channels. Only where extreme cold temperatures prevail year-round and melt is virtually non-existent, such as on the surface of the Antarctic polar plateau, are snow and ice surfaces truly sterile. Organisms are sustained by nutrients and organic matter supplied to glacier surfaces through wind transport of dust, minerals, and organic carbon, and at the base of glaciers where soils, sediments, and vegetation have been overridden during periods of previous glacial advance. Photosynthetic and other autotrophic organisms also produce organic matter that sustains heterotrophic organisms. Specially adapted, cold-tolerant microscopic organisms and macroinvertebrates are common on most glaciers worldwide, including insects (i.e. snow fleas, midges, and flies), worms, copepods, tardigrades, and rotifers (Takeuchi, 2011).

The supra-glacial environment is exposed to high solar radiation and large temporal and spatial variation in meteorological conditions, snow cover, liquid water and nutrient availability, and other factors. Life on glacier surfaces therefore tends to be transient and variable. The dominant primary producers here are snow and ice algae along with cyanobacteria (Anesio et al., 2017). Algae populations grow and cover extensive areas of wet snow and ice surfaces after the onset of melt, varying in color from green to shades of orange and red (Anesio et al., 2017), and together with windblown dust, mineral debris, and black carbon, this acts to significantly to reduce the surface albedo, often enhancing melt (Kintisch, 2017; Fig. 5). Cryoconite holes form locally due to darkening of the surface by a mixture of mineral and organic material, and harbor populations of cyanobacteria that have

Fig. 4 Cryoconite holes on the surface of the Peyto Glacier, Alberta, Canada. The size of these features is roughly of the order 10^{-2} – 10^0 m. Photos: Gennadiy Ivanov.

Fig. 5 Red algae, mineral matter and black carbon, and other organic material darken the ice surface of the Athabasca Glacier, Alberta, Canada. Photo: Mark Ferguson.

importance in sustaining heterotrophic communities where active biogeochemical cycling occurs (Fig. 4; Hodson et al., 2008; Anesio et al., 2017). Biota in these holes also include a diverse range of invertebrates (Zawierucha et al., 2015).

In contrast, the sub-glacial environment has a stable temperature regime, and despite the lack of light, it has several key advantages favorable to microbial life, including the presence of liquid water from surface meltwater and basal melting, and high contact with the glacier bed supplying nutrients and organic matter (Sharp and Tranter, 2017). There exists a range of conditions from well oxygenated to anoxic that creates diverse populations of organisms, from heterotrophic to chemoautotrophic, which further accelerate rock weathering and have major roles in biogeochemical cycling and production of greenhouse gases such as methane and carbon dioxide (Wadham et al., 2010, 2013). As the challenges of sampling in this environment are far greater compared to supra-glacial areas, the understanding and characterization of sub-glacial ecosystems is more limited but, in general microbial diversity deep within and at the base of glaciers is lower than at the surface (Anesio et al., 2017). The recent discovery of isolated hypersaline subglacial lakes under the Devon Ice Cap in the Canadian Arctic has opened up new scientific frontiers, since such lakes have never been observed previously, and these represent an extreme potential microbial habitat that might have extraterrestrial analogs (Rutishauser et al., 2018; see Pascoe, 2019).

Glaciers create distinctive habitats that are often havens for animals and plants, with many different specially adapted mammal, insect, and bird species living on and adjacent to glacier surfaces, and plants colonizing glacier-marginal and recently deglaciated foreland areas (Hambrey and Alean, 1994; Jones et al., 2001; Sale and Michelsen, 2018). Tidewater glaciers and glacier fronts are important foraging areas for terrestrial and marine predators (Descamps et al., 2017). Glacier runoff has an important role in nutrient delivery and influences ecosystem structure over multiple trophic levels in coastal and fjord environments (Arimitsu et al., 2016). Glaciers also influence local and regional climate conditions, maintaining low air temperatures and driving cold, dense

katabatic drainage winds, which affect vegetation growth and diversity. Their meltwater exerts a strong control on the flow and character of proglacial streams and rivers, including variations in volume of discharge, sediment load, redox conditions, electrical conductivity, pH, water temperature, and other characteristics. Therefore, aquatic and terrestrial ecosystems are influenced by glaciers far beyond and downstream from the ice margins (Brittain and Milner, 2001). Their role in moderating stream temperatures is particularly important for maintaining favorable habitat for salmonids and other fish species and invertebrates (Fellman et al., 2014; Milner et al., 2017).

With earlier and more frequent and extensive melt, and the ongoing recession and loss of glaciers under a warming climate, there are a number of anticipated changes to ecosystem functioning and biogeochemical cycling, which may have important feedback effects. Some recent reviews provide detailed insights and summarize the state of knowledge of these changes (Hodson et al., 2008; Hotaling et al., 2017a,b; Milner et al., 2009, 2017; Brighenti et al., 2019; Hock et al., 2019). Increasing availability of liquid water and nutrients across glacier surfaces favors the growth of algae and other microorganisms, both spatially and temporally, in turn reducing the surface albedo and enhancing melt (Hodson et al., 2008; Anesio et al., 2017; Kintisch, 2017; Williamson et al., 2019; Fig. 2). Reduced summer snow cover on glaciers leads to expansion of cryoconite habitats relative to snowpack habitats, and the increase in surface melting and resuscitation of near-surface microorganisms will increase supraglacial ecosystem productivity and organic carbon production (Hodson et al., 2008). The melting and loss of glaciers enhances the release of accumulated organic carbon and other nutrients (nitrogen, phosphorus), as well as anthropogenic contaminants deposited onto glaciers from the atmosphere over many decades (Sharp and Tranter, 2017), with major impacts on downstream aquatic ecosystems (Miner et al., 2017; Milner et al., 2017). With enhanced release of certain contaminants under climate warming, there is increased risk of emerging pollutants to freshwater sources (Chen et al., 2019) and the potential for bioaccumulation through organisms in the ecosystem. Together with shifts in discharge regime and water temperature, the effects of deglaciation are expected to result in a loss of regional biodiversity in microbial and macroinvertebrate communities (Hannah et al., 2007; Jacobsen et al., 2012; Wilhelm et al., 2013; Giersch et al., 2017; Milner et al., 2017; Hock et al., 2019).

Challenges and Priorities

Most glaciers are now responding more strongly to anthropogenic climate warming than to natural forcings (Marshall, 2014; Marzeion et al., 2014a,b). Thus, making reliable projections of future glacier change under different greenhouse gas emission and warming scenarios is a key challenge. There are a number of associated issues to be addressed, such as how fast and to what extent glaciers will change regionally and globally; how this will affect water availability (quantity and timing), water quality, glacier-related hazards, sediment transportation, and aquatic ecosystems; how this will alter global sea levels and their rate of rise, and nutrient fluxes to the oceans; how this will influence local, regional, and global biogeochemical cycles; and how this will feed back to the climate system regionally and globally. An equally important gap in our knowledge is the full range of consequences on people's health, livelihoods, cultures, and social fabrics.

The loss of glaciers is already impacting communities in many parts of the world, particularly in developing countries, prompting local adaptations and mitigation strategies to cope with changes in glacier runoff (see examples in Hock et al., 2019). In the European Alps, many ski and tourism resorts have been attempting to preserve glaciers by covering them with large sheets to insulate and protect the ice underneath, and through other measures such as snow traps and snow farming to supplement the glacier accumulation (see Hester, 2019; Miles, 2019). In other parts of the world, including Argentina and Chile, glacier protection laws have been enacted or considered in an attempt to safeguard against destructive activities such as mining or other resource extraction activities (Anaconda et al., 2018). But globally, further glacier loss cannot be prevented without international commitment and action on greenhouse gas reduction, and even then not likely for several decades or more.

Priorities include improving understanding of the links between glacier dynamics and climate variability, better representing these links in Earth system models, and expanding the observational data needed for assessing and predicting change (Hock et al., 2017). The importance of the ice sheets as a contributor to sea level rise has recently increased relative to that of mountain and polar glaciers (Reager et al., 2016; Bamber et al., 2018), and it is known that the ice sheets and their outlet glaciers are capable of rapid changes in flow speed and calving rate. In areas such as the West Antarctic Ice Sheet, the grounding of the ice below sea level creates an inherent instability that may lead to feedbacks and cascading responses. There is great uncertainty, however, over the future evolution of the ice sheets as measurements are sparse, ice sheet models lack realistic representations of some of the underlying physical processes and of interactions that take place at the ice–bed and ice–ocean interfaces, and there is low confidence in estimates of the warming thresholds required to trigger ice sheet instabilities (Oppenheimer and Alley, 2016; Hock et al., 2017; Meredith et al., 2019). Surface processes (accumulation and ablation) on glaciers and ice sheets are undergoing changes, and representing their spatial and temporal heterogeneity, especially in topographically complex mountain environments, is a challenge. Ablation processes are becoming increasingly affected by factors such as the deposition of dust and black carbon (especially as a result of large-scale wildfire events), as well as algal growth on glacier surfaces; all of which are very poorly handled in current generation models. Accumulation processes are significantly affected by changes in precipitation phase, the incidence of avalanching, snow redistribution by wind, and other factors that are all highly sensitive to changes in air temperature. It is essential that models for local, regional and global-scale projections of glacier mass balance and dynamics are based on physical process understanding as opposed to overly simple or empirical (e.g., temperature-index melt) approaches. This is necessary to capture the inherent process complexities, and sometimes unexpected interactions, feedbacks, and system responses. A further challenge is

in obtaining reliable projections of future climate, especially in mountain regions, at the scale needed to resolve heterogeneity in these processes due to limitations in the downscaling methods used to interpolate results from coarse-scale climate models to the glacier (or sub-glacier) scale (Hock et al., 2019).

Recent advances in remote sensing technologies and a rapid increase in new observations from satellites have greatly improved the monitoring of glaciers and ice sheets and provided much new information but, despite this, there remain significant challenges associated with a lack of adequate observational data (Hock et al., 2017, 2019; Meredith et al., 2019). In polar and high elevation mountain regions there is, in general, a very low density of climate monitoring stations which makes it difficult to assess trends in meteorological variables and to validate climate model outputs. In situ observations and mass balance measurements exist for only a very small fraction of global glaciers, and reference glaciers are typically chosen for reasons such as their accessibility, manageability, safety, and simplicity of their form (Østrem, 2006). As such they may not be representative of the broader regional set of glaciers, and several studies have demonstrated that these glaciers may exhibit notably different behavior than is observed in their regional surroundings (Fountain et al., 2009; Paul and Haeberli, 2008; Carturan et al., 2013; Menounos et al., 2019). This poses a challenge in relating sparse in situ glacier observations to regional scale changes and in explaining inter-glacier variability in behavior, particularly over historical time periods for which remotely sensed geodetic or altimetric observations are not available (Cogley et al., 2013).

Finally, a coupled systems approach is required that integrates physical dimensions of changing ice environments with the human systems that engage with or depend upon them. It is only through investment in coupled systems research and evidence generation that the urgent need for sustainable and appropriate adaptation and mitigation strategies and coordinated efforts demanded by the international community can be achieved, as specified in several recent frameworks including the Paris Agreement (<https://unfccc.int/process-and-meetings/the-paris-agreement/the-paris-agreement>), the UN 2030 Agenda and its Sustainable Development Goals (SDGs) (<https://sustainabledevelopment.un.org/post2015/transformingourworld>), and the Sendai Framework for Disaster Risk Reduction (<https://www.unisdr.org/we/cooordinate/sendai-framework>). Action is needed to build capacity, invest in infrastructure, and make communities more resilient and sustainable (see the call for action by the World Meteorological Organization at its recent High Mountain Summit (<https://highmountainsummit.wmo.int/en>)). Rural, remote, and otherwise marginalized communities, and women in particular, are the most vulnerable and least able to invest in prevention or solutions (Schuster-Wallace and Watt, 2015). Policy and practice therefore require input from these communities and must incorporate local tradition, knowledge, and beliefs to succeed (Schuster-Wallace et al., 2019). Ultimately solutions must involve joint activities and partnerships among researchers, stakeholders, practitioners, and decision makers, and these must utilize transdisciplinary approaches to addressing the complex challenges (Huss et al., 2017; Klein et al., 2019; Schuster-Wallace et al., 2019; IPCC, 2019).

Abstract

Everglades restoration, the largest of its kind in the world, is expected to restore ecosystem functionality and community structure. Anthropogenic changes in peat elevations, water quality, hydrology and habitat loss can make plant and animal recovery difficult. However, our understanding of the complexity of Everglades ecology and the spatial and temporal scales associated with plant and animal requirements for water, is putting the Everglades back on track. The knowledge base for this movement is summarized in this article.

Introduction

Freshwater wetlands all share similar ecosystem structure, functions, and services such as flood tolerant plants, carbon sequestration, and recreational value, respectively. However, the Everglades is one of the more unique wetlands in the world because of its semi-tropical geography, low nutrient biogeochemistry, and complex natural and anthropogenic histories. At the southern extent of the Everglades ecosystem, the value of Everglades National Park (ENP) is globally recognized as an International Biosphere Reserve, Ramsar wetland of international importance and a World Heritage site (with a conservation outlook recently rated as critical; IUCN, 2017). Alpert (2009) found that the Everglades contributes ~\$82 billion of ecosystem services annually, tied to freshwater marshes and associated with services such as water supply and treatment, wildlife habitat, ecotourism, environmental regulation, and land formation.

Historically encompassing 10,000 km², over the past 100 years, the spatial extent of the Everglades has been reduced by over 50% to accommodate the rapidly growing urban population and industrial agriculture in south Florida; dramatically altering the hydrology, chemistry, and biology of this ecosystem (Fig. 1). However, the remnant Everglades is still one of the world's largest wetlands and while in peril, remains a vast "river of grass" supporting a rich diversity of plants and animals, 47 of which are federally- or state-listed as threatened or endangered. Used for water supply, flood control, and environmental preservation, it is impossible to discuss this biome without including its well-documented anthropogenic influences.

The Everglades Historical Geography

The Everglades is comprised of a directionally patterned mosaic of tree islands, shrubs, sawgrass ridges, and aquatic sloughs (King, 1917a,b; Parker et al., 1955). Soil cores from freshwater tree islands (Gleason and Stone, 1994; Willard et al., 2006) document a relatively stable 5000-year-old system as well as very rapid community shifts associated with human encroachment and alterations of the basin hydrology beginning in the late 1800s (McVoy et al., 2011). The first major efforts to drain the Everglades began in 1880, and between 1906 to the 1920s had diverted approximately 2 billion m³ of water to the Atlantic Ocean and drained over 600,000 ha of wetland (Parker et al., 1955; Davis and Ogden, 1994; SFWMD, 1998). By 1940, water tables had declined as much as 3 m, large areas of organic soils had subsided, creating topographic changes of 0.5–2 m at an average rate of 2.5 cm year^{−1}

Fig. 1 Image on the left (A) is the estimated landscape structure of the predrainage (c. 1800) Everglades. Image on the right (B) is the present-day landscape structure. EAA—Everglades Agricultural Area. Modified from McVoy, C.W., Said, W.P., Obeysekera, J., Van Arman, J.A. and Dreschel, T.W. (2011). *Landscapes and hydrology of the predrainage Everglades*. Boca Raton, Florida, USA: University Press of Florida.

(Clayton, 1936; Clayton et al., 1942; Davis, 1943; Stephens and Johnson, 1951; Shih et al., 1979a,b). This extensive soil loss caused concern and led to the construction of levees to impound undeveloped lands (Allison, 1943; Advisory Committee, 1944). The Central and Southern Florida (C&SF) Project was authorized by the United States Congress in 1948 and by 1960 had compartmentalized the Everglades into separate hydrologic units—the Water Conservation Areas (WCAs) and ENP—and partitioned 283,000 ha for the Everglades Agricultural Area (EAA). From 1965 to 1973, additional changes were made in the C&SF Project to meet the Everglades' minimum monthly requirements of water that would have been expected in the 1940s and 1950s. Today the C&SF Project consists of approximately 3220 km of canals and levees, > 600 water control structures, 620 project culverts, and 77 pump stations to manage the water resources of south Florida (SFWMD, 2019). The discontinuous hydrologic subunits created by the C&SF Project (Fig. 1B) each have their own distinctive histories of water depths, flows, and ecological impacts. One of the key impacts has been a dramatic loss of peat. Using GIS data sets to calculate the difference between original and existing peat volumes over the past 150 - years, Hohner and Dreschel (2015) estimated that the historic Everglades had an average peat depth of 2 m, a peat volume of 20 billion m^3 , and a carbon content of 900 million metric tons. By contrast, the current Everglades, with half the original spatial extent and significant soil oxidation, has an average peat depth of only 0.75 m, a peat volume of 5 billion m^3 , and a carbon content of 200 million metric tons.

The Everglades Climate

The health and nature of the Everglades is closely tied to the volume, timing, and distribution of water inflows from rainfall, from Lake Okeechobee, and from agricultural and natural areas surrounding the Everglades. The National Oceanic and Atmospheric Administration (NOAA), United States Geological Survey (USGS), National Park Service, and South Florida Water Management

District (SFWMD) have collected and archived meteorological data in support of regional hydrologic modeling for south Florida (SFWMD, 2005; Brown, 2013), and are presented here as blended point measurements across the Everglades for each $3.22 \text{ km} \times 3.22 \text{ km}$ ($2 \text{ mi} \times 2 \text{ mi}$) grid cell. Climate in south Florida is classified as subtropical with two distinct seasons: a wet season from May to October and a dry season from November to April. The climatological start and end of the wet season are May 22 and October 12, with deviations of ± 3 weeks for the two dates (Swartz, 2019). Average monthly rainfall depths for a 70-year period of record (1948–2018) during the wet season and dry season are 44.5 and 15.2 cm (17.5 and 6.0 in.), respectively.

The primary mechanism producing rainfall are cyclones and wet season daily sea breezes. During the dry season, rainfall is mainly produced by large-scale frontal systems (Swartz, 2019). Fig. 2 is a time series of annual rainfall across three major subareas (WCA-1 and -2, WCA-3, and ENP). Annual average rainfall is 130 cm and can vary from 90 to 200 cm per year. On the average, 75% of the annual rainfall falls during the wet season, while the remaining 25% is accumulated during the dry season. Spatial variation in annual rainfall from one subarea to another can be as high as 50 cm, and decadal trends such as the below average rainfall of 1970 to 1990 have been observed (Fig. 2).

The seasonal pattern of monthly rainfall depths varies slightly across the three major regions (WCA-1 and -2, WCA-3, and ENP) of the Everglades. The northern region (WCA-1 and -2) tends to have slightly wetter dry season while the southern regions has a somewhat bi-modal wet season (June and September). The contrast between dry and wet season rainfall characteristics is well illustrated in Fig. 3, not only in terms of the amounts, but in variability and extreme monthly values. For wet season months, minimum precipitation for each one of the areas is substantially above zero. Of all the months, June tends to be the month with the highest monthly precipitation depth. The largest recorded June rainfall in the southern portion of the Everglades was in excess of 50.8 cm.

Fig. 2 Annual rainfall patterns across the Everglades (WCA-12 is for Water Conservation Areas 1 and 2) (see Fig. 1 for locations).

Fig. 3 Average monthly rainfall patterns for Everglades National Park using boxplot statistics (Helsel and Hirsch, 2002) (see Fig. 1 for locations).

During the winter months from November to March, temperatures can oscillate in the range of 5–28 °C. During the summer months daily temperatures can be as high as 38 °C. High temperatures in combination with wind and the availability of water generates high evapotranspiration (ET) rates, which in many cases equal or exceed rainfall at the annual time scale (Fig. 4). Potential evapotranspiration, computed for a reference crop under no limitations in the water available, helps to designate periods of time when rainfall cannot keep up with ET. Actual evapotranspiration, which is a function of actual vegetative cover and water availability, is much harder to calculate, especially for a system as large as the Everglades. Based upon this uncalibrated reference potential ET, the average annual surplus rainfall was estimated to be 21 cm and the average annual deficit rainfall was estimated to be 37 cm, indicating a small difference between surplus rainfall and deficit rainfall. Although upstream basin runoff keeps the Everglades wet every year, this small difference makes the Everglades sensitive to relatively small climatic changes.

Hydrology

Hydrology of the predrainage Everglades was unique due to the relationship between its topographic characteristics and climate. The slight slope of the topography, 5 cm per km, prevented central or tertiary drainage patterns from forming, which created an even distribution of water flow across the full width of the landscape. The flows were enough to create a multicomponent landscape (e.g. sloughs, sawgrass ridges, and tree islands) with stable elevation differences (McVoy et al., 2011; Said and Brown, 2013). The slope and flow meant that the predrainage Everglades was likely continually draining. The seasonal rainfall distribution meant the Everglades was a seasonally pulsed system. The balance between the seasonal inflow and outflow was such that each year's wet season arrived before the system dried out. The water depths within sloughs throughout the ridge and slough landscape (RSL) typically rose and fell each year from a low of about 30 cm to a high of about 90 cm (Fig. 5); an environment that could support long-lived aquatic organisms (McVoy et al., 2011; Said and Brown, 2013). Hydrologic characteristics of the predrainage

Fig. 4 Monthly rainfall patterns averaged across the WCAs and ENP from 1948 to 2018, compared to the average monthly rates of potential evapotranspiration indicating times of rainfall deficits and surpluses. Potential evapotranspiration was computed from measured temperature, relative humidity, solar radiation, and wind speed from a reference grass crop under no limitations in the water available.

USACE and SFWMD (2014). Comprehensive Everglades Restoration Plan, Central Everglades Planning Project final integrated project implementation report and environmental impact statement. Jacksonville, Florida, USA: United States Army Corps of Engineers; and West Palm Beach, Florida, USA: South Florida Water Management District.

Everglades were synthesized into references ranges of inundation duration (hydroperiod) and seasonal range of minimum and maximum water depths or amplitude by McVoy et al. (2011) (Table 1).

The artificial infrastructure managing water in the remnant Everglades removes natural connectivity, creates preferential flowways and diverts upstream inflow, which all result in generally reduced water levels and greater frequency of drying and drought conditions within the Everglades marsh. The current flow and depth characteristics relative to the predrainage characteristics (Table 1) indicate that the extant Everglades is significantly drier (i.e., shorter hydroperiods) by 4–10 months, especially in ENP. The seasonal minimum water depths are also indicative of a drier extant landscape; they are lower than the historic ranges by 0.2–0.55 m in WCA-3A and by 0.3–0.6 m in ENP. The extant Everglades is also more variable than the historic Everglades. Due to impoundment, the current seasonal maximum water depth in central WCA-3A is much higher than the current ENP and is twice the depth of the historic RSL. At the same time, the minimum water depth varies between 0.03 and 0.6 m indicating that this region is often deeper than the historic landscape. A focus of Everglades restoration is to mimic the historical hydroperiod and seasonal maximum and minimum by increasing total flows from upstream watersheds to ENP.

Geology

Four main geological formations—Tamiami, Fort Thompson, Anastasia, and Miami—underlie the Everglades. The porosity of these formations to groundwater is spatially variable and contributed to their development and vegetation patterning. The northern section of the Fort Thompson underneath the historic sawgrass plain is less porous, while the southern section of the Fort Thompson under the RSL system is more porous and may have contributed to heterogeneous flow speeds and creation of Everglades iconic patterned system (Parker et al., 1955).

Limestone is the predominant bedrock of the Everglades, with some sandy areas on the eastern region. Therefore, groundwater has a higher ionic content than surface water, and in some cases extremely high if it encounters relict seawater (Renken et al., 2005; Harvey and McCormick, 2009). Dependent on the overlying soil characteristics, the karstic nature of the groundwater can influence the surface chemistry of the ecosystem. In the historically shallow sloping flat Everglades landscape, areas of continuous thick peat had a relatively high resistance to vertical water flow, allowing little exchange between the bedrock and surface soil layers (Gleason and Stone, 1994; Harvey and McCormick, 2009). In areas of shallow peat and on the western side of the Everglades, Newman et al. (2017) suggest that there is connectivity to the underlying bedrock, and surface waters and soils are influenced by the mineral rich groundwater.

In the remnant Everglades, the northernmost impoundment (WCA-1), is unique because in its interior it is a soft water, ombrotrophic system (i.e., most moisture and nutrients come from precipitation). Some believe that WCA-1 is ombrotrophic today because it is completely enclosed within the levees and canals and does not experience natural sheetflow (Willard et al., 2006). However, because of its location in the landscape, deeper peat deposits (depth 3 m) and resultant higher elevation, WCA-1 would naturally become isolated from surface and groundwaters, resulting in ombrotrophy (Harvey and McCormick, 2009). The paleoecological record suggests immediately downstream of WCA-1, WCA-2A was also soft water. Indicators of a more acidic environment were found in WCA-2A soils deposited prior to impoundment (1961), but were absent postimpoundment (Slate and Stevenson, 2000). Water entering WCA-2A, either through the canal system or via groundwater discharge under the levee system has become enriched in minerals, and the ecosystem switched to one where calcareous algae and cyanobacteria dominate, as opposed to soft water desmids (McCormick and O'Dell, 1996; McCormick et al., 2001; Gaiser et al., 2011; Hagerthey et al., 2011, 2012). Thus, the connectivity between surface water and groundwater in this karst system, whether through stage differentials or direct discharge, means increased water quantity for Everglades restoration in many areas will also be associated with increased mineral composition (Newman et al., 2017), unless decompartmentalization can eliminate some of these interactions.

Biogeochemistry

The historic Everglades primarily received nutrients via atmospheric deposition and with no source of phosphate from mineral rock weathering; it evolved as a phosphorus limited ecosystem (Noe et al., 2001). Any available phosphorus in the water column is rapidly cycled by the microbial community (Noe et al., 2003; Scinto and Reddy, 2003), before ultimately being stored in sediments. In areas with high mineral content, calcium-bound phosphate is the dominate inorganic form (Chambers and Pederson, 2006), but generally organic-bound phosphorus is the dominant form of phosphorus stored in the Everglades (Qualls and Richardson, 1995; Reddy et al., 1998, 2011).

Under low phosphorus conditions, organisms evolve strategies to acquire phosphorus when it is not typically available. For example, sawgrass and oligotrophic algal species produce phosphatase enzymes that enable the use of organic phosphorus compounds as sources of phosphate to support growth (Kuhn et al., 2002; Newman et al., 2003; Sharma et al., 2005). As a result, anthropogenically increased phosphorus loading has had a dramatic effect on the Everglades (Davis, 1994; Craft and Richardson, 1997; Crozier and Gawlik, 2002; McCormick et al., 2002; McCormick and Laing, 2003; Gaiser et al., 2005; Sklar et al., 2005; Hagerthey et al., 2008; Newman et al., 2017). Some of the most visual changes are the loss of phosphorus sensitive periphyton assemblages; particularly calcareous periphyton, and the replacement of the RSL by dense stands of southern cattail (*Typha domingensis*, Newman et al., 1998; Hagerthey et al., 2008; Fig. 6). While native to the ecosystem, cattail historically occurred in sparse stands or was associated with disturbed areas such as alligator holes (Davis, 1943, 1994; Loveless, 1959), it did not exist over tens of thousands of hectares of almost monotypic stands as it does today (Rutchey et al., 2008; Sklar et al., 2009, 2011).

With the first prototype completed in 1993 (Guardo et al., 1995), a series of stormwater treatment areas (STAs), constructed wetlands, were built on the boundaries of the Everglades, to remove phosphorus before it enters the ecosystem. Currently encompassing 23,000 ha of wetland treatment area, over the last 24 years, these STAs have treated ~6.6 trillion gallons of surface water and retained 2604 metric tons (Chimney, 2019), resulting in significant reductions in phosphorus inputs to the Everglades. While dense cattail stands are still prominent, there is evidence that the rate of expansion may be decreasing in response to phosphorus load reductions (Rutchey et al., 2008; Zweig and Newman, 2015).

Habitats

Ridge and Slough Landscape (RSL)

The Everglades RSL is a patterned/corrugated peatland with parallel drainage topography and is the dominant landscape type (Fig. 7). The RSL was created as a result of water flow, sediment dynamics, and differential production and decomposition, and has been relatively stable for thousands of years (Bernhardt and Willard, 2009). The RSL consists of long, linear ridges of sawgrass (*Cladium jamaicense* Crantz.); longer hydroperiod sloughs—open water areas with white water lily (*Nymphaea odorata*), submerged aquatic vegetation, and short-statured emergent species such as spikerush (*Eleocharis* spp.); and occasional tree islands oriented parallel to the slow-moving flow of water from northwest to southeast. The microtopography is very important (see Faunal

Fig. 6 Aerial image of WCA-2A showing dense cattail (forefront) transitioning to a patterned ridge and slough landscape with low phosphorus conditions found in areas distant from inflow structures. Photo credit: Mark Cook.

Communities) however, ridges are only 10–50 cm higher than sloughs. Historical microtopography was nearer to 1 m (McVoy et al., 2011). Fragmentation due to compartmentalization, impoundment, and reduced flows (Ogden, 2005) can explain this degradation (Wu et al., 2006; Nungesser, 2011; Zweig et al., 2011).

The RSL includes two types of wet prairie communities—marl and organic peat based (Fig. 8). Marl prairies are unique to the southern Everglades and are characterized by reduced hydroperiods, short-stature sawgrass, Muhly grass (*Muhlenbergia filipes*), and calcareous periphyton on marl or exposed limestone. The peat-based prairies occur in hydroperiods between marl prairies and sloughs and consist of the similar species to sloughs but in different densities. In peat-based prairies, the dominant plant is spikerush, followed by white water lily, maidencane (*Panicum hemitomon*) and Egyptian paspalidium (*Paspalidium geminatum*).

Tree Islands

Tree islands are a very distinctive, elevated Everglades feature (Fig. 9). Dominated by woody vegetation, this habitat currently rises some 30 cm above the surrounding marshes and although some islands rise more than 150 cm, most are 50 to 100 cm lower than they were historically (McVoy et al., 2011).

Although tree islands occupy only a small portion of the freshwater Everglades (3.8 to 14%, references in Wetzel et al., 2017) they are home to more than 50% of the animal biodiversity (Meshaka et al., 2002), especially birds (Table 2).

Tree islands come in two basic shapes (Fig. 10). Pop-up or battery islands have an elevation gradient radiating out from a high elevation center to low elevation peripheries. The elevation gradient on fixed or pedestal islands proceeds from a high elevation upstream head to a low elevation downstream tail (Fig. 10A).

In addition, the high elevation head is a significant zone of increased phosphorus storage and accumulation decreases toward the downstream tail (Fig. 11). Storage on tree islands is several-fold higher than the adjacent marsh, and it is postulated tree islands function as phosphorus sinks and thus regulators of Everglades oligotrophy (Wetzel et al., 2005, 2011; Ross et al., 2006).

Everglades tree islands exhibit a wide range of tolerances to fluctuating water levels (Fig. 12). Tree species, such as *gumbo limbo* (*Bursera simaruba*) and *white stopper* (*Eugenia axillaris*) are intolerant of high water levels and long hydroperiod; therefore, they are typically found in areas that are inundated only infrequently. On the other hand, species such as *willow* (*Salix caroliniana*) and *pond apple* (*Annona glabra*) tolerate high water levels and long hydroperiods; therefore, they are found in areas that are flooded

(B) Development of a pop-up battery tree island: (1) peat detaches due to buoyancy provided by microbial gas, (2) peat battery drifts during periods of high wind and water, (3) floating battery islands rest slightly above the water's surface and are colonized by terrestrial plants. (C) Characteristic battery island with maximum elevation in the center of the island. Source: Wetzel, P.R. (2002). *Tree Island Ecosystems of the World*. In Sklar, F.H., and van der Valk, A. (eds.) (2002). *Tree Islands of the Everglades*, pp. 19–70. Boston, Massachusetts, USA: Kluwer Academic Publishers. Figs. 2–5, page 44.

Fig. 11 (Left) Pedestal tree islands often have an irregular rock outcropping below the peat on the head of the island where nutrients accumulate more than 100 times that found in the surrounding marsh. (Right) The flow of nutrients on a fixed tree island is a function of surface and groundwater direction. The accumulation of nutrients is due to wildlife transference, particulate capture by dense trees on the head, and the ability of trees to transpire phosphorus from the underlying groundwater and limestone. Modified from Wetzel, P.R., van der Valk, A.G., Newman, S. et al. (2005). Maintaining tree islands in the Florida Everglades: Nutrient redistribution is the key. *Frontiers in Ecology and the Environment* 7(3), 370–376.

10–12 months a year. Species that are adapted to the wettest conditions can occur over relatively wider ranges of hydrologic conditions compared to less flood-tolerant species.

When hydrologic conditions on an island are altered for extended periods, the extant species lose their competitive advantage. The time required for a tree island community to significantly shift in response to altered hydrology is not clear but seems to vary from 10 to 25 years. In WCA-2A, initial over drainage from 1920 to 1950 caused a conversion of predrainage sloughs to shallower wet prairies (Loveless, 1959; Goodrick, 1974). The levees constructed between 1955 and 1964 increased water depths by some 0.75 m causing 90% of the tree islands in WCA-2A to “drown” due to excessive inundation, converting them to sawgrass ridges (Dineen, 1972; Worth, 1988; Sklar and van der Valk, 2003). Tree islands also “drown” when overgrown by invasive plants

Fig. 12 The mean hydroperiod and hydroperiod range for dominate tree species from 73 tree islands from Everglades National Park and Water Conservation Areas 3A and 3B.

such as, *Lygodium microphyllum*, an invasive Old World climbing tree fern that can make a tree island uninhabitable. Some 50% of the islands in WCA-1 are infected by this fern (Volin et al., 2004).

Mangroves

Mangroves are a unique vegetation of forested tropical wetlands that dominate the tropical and subtropical coastal areas (Fig. 13), broadly between 25°North and 25°South latitude (Lugo and Snedaker, 1974; Tomlinson, 1986). While there are 10 species of mangroves in the New World (Smith, 1992), species richness in the Gulf of Mexico and Caribbean region is low, and only four mangrove species are commonly found in the Everglades at the transition between marine and freshwater biomes. They include red mangrove (*Rhizophora mangle*), black mangrove (*Avicennia germinans*), white mangrove (*Laguncularia racemosa*), and buttonwood (*Conocarpus erectus*) (Britton and Morton, 1989).

Mangrove forests in the Everglades are distributed along the southern extent of ENP (Fig. 14) covering an area of 144,447 ha with a total standing biomass of 5.6×10^9 kg (Simard et al., 2006). Unlike most mangrove forests of the world that receive significant inputs of terrigenous sediments and develop along deltaic gradients (Thom, 1982), Everglades mangroves receive extremely low upland sediments and nutrients (especially phosphorus) and develop along carbonate gradients (Woodroffe, 1992). In the Everglades, mangrove productivity is a function of freshwater flow and the organic content of the soil. Mangroves growing on historic freshwater peats of Shark River Slough are significantly larger, denser, and more productive than those growing on the low peat, carbonate soils of Taylor Slough (Fig. 14).

Fig. 13 Schematic marine-terrestrial transect showing the different plant communities, including mangroves, distributed along the transect. Figure was modified from a 1971 ENP brochure, Everglades Wild Guide Handbook, by Betty Fraser.

Fig. 14 Mangrove regions show up as a *green* fringe along the Gulf of Mexico and Florida Bay and include riverine-like forest distributed along Shark River Slough and the scrub mangroves distributed along northeastern Florida Bay and Taylor Slough.

The ability of these mangroves to compensate for sea level rise and maintain current shorelines has been compromised by freshwater diversions upstream (Ross *et al.*, 2000; Meeder and Parkinson, 2018). In southeast ENP, a broad band of mixed graminoid-mangrove and sawgrass communities has shifted inland by 3.3 km between 1940 and 1994 (Ross *et al.*, 2000), and using a combination of 1930s aerial photography and recent satellite imagery, Meeder and Parkinson (2018) measured an average rate of mangrove intrusion in the same region of 31 to 20 m year⁻¹, between 1938 and 1968. Projects designed to move more water to the southern part of the Everglades will hopefully prevent further migration and create conditions that allow mangroves to develop soil at a pace that keeps up with future sea level rise (Sklar *et al.*, 2019).

Faunal Communities

Though the Everglades is set climatically and geographically within the subtropics, its native faunal community is comprised largely of North American temperate species and few species from the adjacent Caribbean Basin. This is most notable for the terrestrial and freshwater taxa such that all freshwater fish species, and most species of freshwater invertebrates, amphibians, reptiles, terrestrial mammals (except for some species of bats), and breeding land birds originate from the coastal plain of the southeastern United States. Species that originate from the West Indies tend to belong to taxonomic groups that have the natural capacity to disperse across open water (Rader, 1999) either by flight (birds, bats, lepidopterans, odonates, and other terrestrial invertebrates), passive drifting by ballooning (spiders), or swimming (West Indian manatee *Trichechus manatus*). Only a limited number of terrestrial avian species from the West Indies are permanent residents, perhaps because of a lack of suitable upland habitat, but many species of waterbirds that breed in the Everglades are distributed throughout the neotropics (Robertson and Kushlan, 1984). The Everglades can clearly support freshwater species of neotropical origin as demonstrated by the large numbers of nonnative fauna that have become established in the Everglades through human assistance (e.g. Schofield *et al.*, 2009).

Animal species diversity in the Everglades is relatively low (except for some arthropods groups) and is typically characterized by a few dominant species for each taxonomic group. For instance, the number of species of freshwater fish (Loftus and Kushlan, 1987; Trexler, 1995), macroinvertebrates, and reptiles and amphibians (Means and Simberloff, 1987) are lower than in comparable habitats on the Florida Peninsula and elsewhere. The Everglades supports relatively high numbers of mammalian carnivore species but fewer bats and rodents compared to northern Florida (Layne, 1984). A similar pattern is evident for terrestrial birds, with southern Florida attracting fewer breeding land birds than northern Florida and about more than half the number of species of some northern states; however, numbers of species of breeding waterbirds are relatively high (Robertson and Kushlan, 1984). The Everglades is also characterized by relatively few endemic species. Notable subspecies include the Everglades snail kite

(*Rostrhamus sociabilis plumbeus*) and Everglades mink (*Mustela vison evergladensis*), which are found throughout southern Florida, and the Cape Sable seaside sparrow (*Ammodramus maritimus mirabilis*), which has a far more limited distribution comprising just six subpopulations within ENP. Threatened or endangered species within the Everglades Biome include West Indian manatee, Florida panther (*Felis concolor coryi*), wood stork (*Mycteria americana*), Everglades snail kite, Cape Sable seaside sparrow, American crocodile (*Crocodylus acutus*), Bartam's hairstreak butterfly (*Strymonas bartrami*), and Schaus' swallowtail (*Heraclides aristodemus ponceanus*). The depauperate diversity and limited endemism are probably related to the isolated location of the Everglades at the tip of the 644 km long Florida peninsula (Means and Simberloff, 1987) and the young age of the Everglades (less than 6000 years old), which has provided a limited period of continuously favorable conditions necessary for speciation and immigration. Moreover, the extremes of temperature and frequent drying that occur in the Everglades' freshwater habitats and the limited availability of terrestrial habitats possibly preclude the establishment of many species (Layne, 1984; Robertson and Kushlan, 1984; Loftus and Kushlan, 1987).

Freshwater communities in the Everglades are dominated by macroinvertebrates (e.g. aquatic beetles, odonates, crustaceans, and planorbid snails), amphibians (i.e. frogs and salamanders), and small (< 4 cm; Poeciliidae and Cyprinodontidae) and large (Centrarchidae) fishes. Fish and crayfish play an especially important role in the food web by supporting some of the Everglades' most charismatic top predators such as alligators and wading birds (Boyle et al., 2012, 2014). Surprisingly, estimates for fish and invertebrate standing stocks in the Everglades are among some the lowest recorded for freshwater aquatic habitats despite the relatively high primary productivity of the periphyton (Turner et al., 1999). This is partly because of the physiological stress experienced by aquatic animals in the seasonally drying wetlands (Kushlan, 1976), but arguably more important is the inedibility of the calcareous periphyton mats (Browder et al., 1994; Geddes and Trexler, 2003; Chick et al., 2008). A significant proportion of the energy and nutrients moving through the food web appear to be transported via less efficient detrital pathways rather than consumption of primary producers (Williams and Trexler, 2006; Hagerthey et al., 2014).

Aquatic animals survive drying during the dry season either by moving to lower elevation aquatic refugia such as alligator holes and creeks (e.g., all freshwater fish), or by tolerating it through burrowing (crayfish), diapause (copepods and cladocerans) or aestivation (e.g. gastropods) (Gaiser et al., 2012). At least one crayfish species (*Procambarus fallax*) appears to use a joint strategy, first moving downslope from drying habitats to aquatic refugia and then burrowing when refugia are no longer available (Cook et al., 2014). The faunal community can experience high mortality depending on the severity and duration of the drydown (Trexler et al., 2005; Dorn and Cook, 2015). Recolonization rates vary by taxa, but population recovery typically take several years following reflooding (DeAngelis et al., 2005; Trexler et al., 2005).

Predator limitation on prey is a strong driver in the freshwater Everglades. Predatory sunfishes can limit small fish, crayfish and shrimp populations (Dorn et al., 2006). Dorn and Cook (2015) experimentally demonstrated that abundances of large predatory fish were seasonally reduced in marshes disturbed by moderate drying, and the response of small fish densities to this predator release was minimal, however slough crayfish (*P. fallax*) densities, which were similar across all wetlands before drying, increased almost threefold after the disturbance. The strength of predator control in the Everglades can shift through time and in space according to recent hydrological conditions. This creates variable environments for fish and crayfish population growth. This in turn, generates flexible food web reconfigurations that cascade upwards to provide variable foraging conditions for nesting wading birds. For example, whereas the Everglades' most abundant species of wading bird, the white ibis (*Eudocimus albus*), fuels its nesting colonies primarily with crayfish (Boyle et al., 2014), wood stork, snowy egret (*Egretta thula*), and tricolored herons (*E. tricolor*) almost exclusively feed fish to their young (Ogden et al., 1976; Boyle et al., 2012).

The Wading Bird Paradox

Although standing crops of small fishes and macroinvertebrates in the Everglades are relatively low, the Everglades can support unexpectedly large populations of top predators (Turner et al., 1999). Of note are the exceedingly large populations of nesting wading birds (orders Ciconiiformes and Pelicaniformes) that, in a given year, can exceed a hundred thousand nesting pairs (Ogden, 1994; Cook and Baranski, 2019). The key process limiting wading bird nesting in the Everglades is the availability of aquatic prey (Frederick and Ogden, 2001; Herring et al., 2011), which is a function both of prey production and how accessible prey are to capture by birds. The reason that the limited secondary production in the Everglades can support such large numbers of birds is because wetland topography and landscape-scale seasonal drying can interact to concentrate prey at extremely high densities and provide critical foraging conditions at the appropriate places during the winter/spring breeding season (Fig. 15).

Restoration Underpinnings

Impacts to the natural Everglades ecosystem resulted in a strong public desire to restore the Everglades and the implementation of the Comprehensive Everglades Restoration Plan (CERP) in 2000, with the goal of protecting, preserving and restoring this ecosystem. To support Everglades restoration, SFWMD developed a group of computer models to characterize the predrainage and postdrainage/managed Everglades system. These "Regional Simulation Models" (RSM) estimate the hydrology of

Fig. 15 Wading birds foraging in the Everglades ridge and slough on high densities of prey that became concentrated by landscape-scale seasonal drying. Photos credit: Mark Cook.

Fig. 16 Flow characteristics of the predrainage, postdrainage, and restored Everglades.

approximately 31,000 km² (3.1 million ha) of south Florida, including Everglades wetlands, in their current state and as they existed before drainage (ca. 1850). The model is used to indicate relative changes in hydrology between predrainage and current conditions and used in an adaptive management framework to help guide water management and project planning (Said and Brown, 2013). CERP changes to the south Florida infrastructure of canals, levees, and pumps is expected to increase the average volume of water to the parched Shark Slough of ENP by 63% (666.1 million m³) but is not expected to reach historic levels (Fig. 16).

Conclusion

The complexity and trade-offs required to ensure the anthropogenic and natural resource demands of the Everglades ecosystem are met can appear daunting (Sklar et al., 2005). Particularly given that in some cases even natural needs can be in conflict, e.g., low seasonal water requirements for the cape sable sparrow versus higher water needs for aquatic fauna. However, the ecosystem is resilient and while damaged, it can recover. In 2018, wading and migratory birds nested on scales seen over 100 years ago (Cook and Baranski, 2019).

Abstract

This paper represents a status assessment of the Hawaiian archipelagos wetlands including the current status, stressors, and future viability. Wetlands in the Hawaiian archipelago encompass all fresh and saline lentic (standing or still water) ecotypes occurring from sea level to upper elevations. Wetlands can be separated into two categories: wetlands (bogs, upland marshes and swamps; lowland freshwater and saline marshes, and estuaries) (Polhemus et al., 1992) and water bodies (ponds, fresh and saline lakes, anchialine pools, and artificial reservoirs). Historically, wetlands were located on all of the main Hawaiian islands and a few of the Northwestern Hawaiian Islands (NWHI). Currently, wetlands are still found on all the main Hawaiian Islands and Midway and Laysan in the NWHI. However, the quality of many of these wetlands is now comprised of non-native vegetation, invertebrates, and fishes. In addition to naturally formed wetlands and water bodies, artificial reservoirs (i.e., wastewater treatment plants and stock ponds) are also classified as wetlands in the main Hawaiian islands. Our assessment of wetland viability, defined as the likelihood of persistence over the long term, is based on the concepts of representation, redundancy, and resiliency. The main stressors of wetland viability are development and altered hydrology, recreation and human access, water pollution, invasive animals and plants, sea level rise, flooding and erosions, natural disasters (i.e., hurricanes), and drought. Ongoing conservation efforts are helping to protect remnant patches of natural

wetlands in the Hawaiian archipelago. The conservation of these habitats depends largely on combined efforts of State, Federal, multi-agency organizations, non-profit organizations, and the voluntary support of private landowners. An analysis of four future scenarios identified a decline in wetlands viability in lieu of intensive management.

Introduction

This document is an overview in the wetlands and fresh and saline open water bodies in the Hawaiian archipelago and describes the ecological factors that have influenced the habitat over time. An introduction to the Hawaiian archipelago including geography, formation, climate, hydrology, island names and descriptions, can be found in the chapter on the Physical Geography of the Hawaiian Islands by Harrington included in this work. Other biome publications that influence wetlands and open water bodies in Hawai'i are "The Stream Systems of Hawai'i," "The Coastal Systems of Hawai'i," "The Wet Forest Systems of Hawai'i," and "Anthropogenic changes—The Developed System of Hawai'i."

Wetland and Open Water Body Description.

Wetlands and open water bodies occur in Hawai'i from sea level to elevations of at least 1525 meters (m) (Table 1). In general, wetlands and open water bodies in Hawai'i function (physically, chemically, and biologically) in similar manner as lentic ecotypes around the world. Similarly, they also do not function because of activities such as water diversions, groundwater withdrawals, and paving of nearby surfaces. The functions of wetlands and open water bodies in Hawai'i's are influenced by the tropical climate conditions (high year-round temperatures and precipitation), porous volcanic soil and steep terrain, which can increase rates of evapotranspiration, organisms respiration, soil weathers, and ground-water recharge. These differences suggest that relationships and models from temperate wetlands and open water bodies may not be uniformly applicable to wetlands in Hawai'i.

For this assessment, open water bodies, or "loko," are ponds, lakes, and any enclosed body of water with areas of open water (Pukui and Elbert, 1986; Apple and Kikuchi, 1975), with generally <25% cover of vegetation or soil (Polhemus et al., 1992). Also included are sub-types such as anchialine pools and artificial reservoirs that do not necessarily fit the standard definition of a wetland (i.e., little to no hydric soil). However, these have been included due to other "wet" similarities and also due to all habitat supporting similar organisms (e.g., aquatic insects, waterbirds, hydrophytes).

In the Hawaiian archipelago, naturally-formed bodies of open water occur in basins that are primarily volcanic in nature and substrate. In addition, there are a few naturally-formed open water bodies resulting from ancient climatic events such as lakes on nonporous coral islands and others created by melting of glaciers. They are also dependent on the same above and below ground water sources as wetlands. However, at higher elevation, along with precipitation and fog drip, snow melt also drains into alpine lakes. At lower elevations near the coast, storm or tidal waves and sea spray with continued evaporation may create a hypersaline condition (Schauinsland, 1899; Ziegler, 2002).

Naturally-formed wetlands and open water subtypes can have shoreline and substrates varying from solid rock to sandy, hydric soils. All of which can be influenced by climate, topography, organism in and around water bodies, time, and human manipulation.

In Hawai'i, the presence of hydric soils is a good indicator of wetland presence. However, it should be noted that not all areas containing hydric soils are considered wetlands. Other factors such as vegetation and hydrology must also be present. Some areas with hydric soils as shown on the maps are actually considered wet forest. The standard references for drainage classifications and permeability rates of soils in Hawai'i are contained in U. S. Department of Agriculture (USDA) Natural Resource Conservation Service's (NRCS) soil surveys.

Unlike wetlands which require hydric soils as a substrate, naturally-formed bodies of open water usually require a non-porous substrate like rock or coral. Anchialine pools are an exception, and are dependent on underground movement and flow of water and thus require porous volcanic or limestone substrates. In Hawai'i, the volcanic basalt parent material and derived minerals are extremely porous, and ancient limestone coral uplifts or karst material are full of cracks and crevices allowing water to drain to a water table, deep below the surface (Maciolek, 1969). At lower elevations, a water table near the surface can allow water to collect in an above ground basin. At high (alpine) elevations, Wentworth and Powers (1941 in Massey, 1978) have suggested naturally-formed basins were sealed by ice.

Plants and animals found in a particular wetland are also likely to be found in open water bodies that have similar topography, climatic conditions, salinity levels, shoreline and bottom substrate, surrounding habitat usage and water input. Exceptions to this are the anchialine pools. Due to the wide variety of locally unique algal and bacterial types these pools are generally the only open water bodies that provide habitat for individually unique assemblages of organisms (Yamamoto et al., 2015).

Pre-Human Condition

Information on the quality and extent of wetlands and open water bodies across the Hawaiian archipelago especially in NWHI prior to human settlement is limited to non-existent. While the main islands of Hawai'i were inhabited, eight of the ten NWHI have no physical evidence of habitation by native Hawaiians (Ziegler, 2002). Although the knowledge of islands northwest of Nihoa and Mokumanamana could be implied thru mo'olelo (stories) and mele (chants and songs) there is no record of settlements by native Hawaiians. Therefore, the wetlands and open water bodies on those islands remained unchanged by humans until contact with Westerners.

Due to the great long-term ecological stability in the Pacific islands prior to human contact (Steadman 1995 in Athens, 1997), it can be assumed that wetlands and open water bodies found in Hawai'i historically are the same as found today. The porous and permeable basalts substrate that forms the bulk of the main islands of Hawai'i facilitate infiltration and storage of groundwater. A large body of groundwater exists within these porous basalts at lower elevations throughout the interiors of the larger islands. In addition to this basal groundwater layer, smaller perched groundwater systems form at higher elevations, contained by dense geological features of low permeability. As such, many of the geographic locations for certain sub-types such as lakes, bogs, and upland marshes and swamps have remained the same. For instance, in 1982, Maciolek identified lakes in the Hawaiian archipelago that still exist from prehuman contact (Table 5). Historically, we can assume there were more bodies of open water than at present, since Maciolek (1982) considered Ālia pa'akai "Salt Lake" and Ka'elepulu Pond on the island of O'ahu, and Mānā Plain on the island of Kaua'i to be extinct. Therefore, for this section we simply state that most of the wetlands and open water bodies used in this analysis existed prior to human contact and likely in greater numbers.

With the assumption that wetlands and open water bodies were present and functioning throughout the Hawaiian archipelago as defined in Table 1, the habitat for native animals was present (Table 2). Therefore, with the lack of genetic dating for all native species, we assume all native species were present in wetlands prior to human contact and likely in greater numbers.

Montane Bog

Though absent on Ni'ihau and Lāna'i, these bogs were scattered throughout the higher elevations of the other main Hawaiian islands (Table 3). These bogs were characterized by irregular, hummocky cushions of low-growing native sedges, and grasses, in addition to a diversity of unique bog tolerant plants (Table 4). The most unusual aspect was the presence of dwarf individuals (often less than about 10 cm high) of *Metrosideros polymorpha* var. *pumila* ('ōhi'a) and *Vaccinium reticulatum* (ohelo 'ai, Hawaiian blueberry). A widespread Northern Hemisphere bog species of insect-eating *Drosera anglica* (mikinalo, or Sundew) also naturally colonized certain Kaua'i bogs (Cuddihy, 1989 in Stone and Stone, 1989; Ziegler, 2002).

Each bog is distinct and contains a unique assemblage of native plants. The windward slopes of Mauna Kea on the island of Hawai'i contain large expanse of a very wet 'ōhi'a community that has been described as "bog-formation dieback." In such systems on water-soaked soils, stands of 'ōhi'a trees undergo dieback and are replaced by sedges and 'ōhi'a shrubs (Mueller-Dombois, 1986). The botanically rich bogs of east Maui were comprehensively detailed by Loope et al. in 1991. An east Maui montane bog, surrounded by *Deschampsia* grassland was characterized as "alpine" by Vogl and Henrickson (1971) but still has much in common with those found at lower-elevations.

Kaua'i's Kanaele Bog is the State's only lowland (640 m) bog community. Among the rare and endangered plant species found at Kanaele are a species of 'ōhā wai, *Dubautia herbstobatae* (na'ena'e), kāmakahala, a native bog violet, and a native thistle (The Nature Conservancy of Hawai'i, 2019).

Upland Marshes and Swamps

Upland marshes were less common than upland bogs and dominated by hydrophytes (Table 4). A major distinguishing feature was the absence of trees and shrubs. Marshes in the upper Ko'olau Mountains such as Ka'au Crater (O'ahu) fall into this category.

Upland swamps occurred on all the main Hawaiian islands except for Lāna'i. The major feature separating upland swamps from upland bogs and marshes is the presence of trees (Table 4).

Lowland Freshwater Marshes

Lowland freshwater marshes were among the most extensive lowland wetland ecosystems in the main Hawaiian islands, although they tended to occur to the greatest extent on the older islands of O'ahu and Kaua'i. Growing in these wetland sites and forming a dense sod around the margins are *Schoenoplectus lacustris* subsp. *validus* ('aka'akai), *Paspalum vaginatum* (seashore paspalum), and *Bacopa monnieri* (water hyssop) (Gagne and Cuddihy, 1999). An extensive list of wetland plants found in the State of Hawai'i can be found in Lichvar et al., 2016.

Lowland Saline Marshes and Estuaries

This wetland sub-type was believed to be extensively represented in the main Hawaiian islands, especially on Maui, Moloka'i, O'ahu, and Kaua'i. Examples of marshes included: Ninole Springs, Hilea, and Honu'apo, on the island of Hawai'i; Kanahā Pond and Keālia Pond, on the island of Maui; Pala'au, on the island of Moloka'i; Pearl Harbor and Waikiki on the island of O'ahu; and Hule'ia Marsh, on the island of Kaua'i. Vegetation commonly found in these wetlands include grass, *Paspalum distichum*, *Sporobolus virginicus*, sedges such as *Cyperus javanicus*, *C. Laevigatus*, *eleocharis* spp., *Fimbristylis cymosa* and others (Stemmermann, 1981).

Some examples of estuary ecosystems in Hawai'i included: Waipi'o Bay and Waiakea Pond (island of Hawai'i), Keālia Ponds (island of Maui), Maui; Kāne'ohe Bay (island of O'ahu), O'ahu; and Wainiha Bay (island of Kaua'i).

Table 1 Definitions of wetlands and water bodies included in this assessment.**Wetlands**

High elevation or montane bogs—Generally form above 460 m elevation on the northeastern flanks of mountains exposed to prevailing wind and rainfall averaging from 300 to 1000 cm. Small, self-contained bodies of open water found in flat, mid- to upland areas with high persistent rainfall (>500 cm a year). Precipitation also includes fog drip and snow melt on the island of Hawai'i and Maui. The water is acidic, clear, cool, very low in dissolved minerals, and yellow to brownish in color. Saturated soils sit atop a layer of peat which have a layer of clay beneath which inhibits drainage (Polhemus et al., 1992) and a hard iron precipitate within the top 60 m of the soil surface that increases ponding and saturation above that layer (Gagne and Cuddihy, 1999). Bogs have few or no trees or hydrophytes (aquatic plants) and are dominated by mosses and grasses

Upland marshes—Perennial to seasonally intermittent non-forested wetlands in upland areas (100–1200 m) of moderate to high rainfall, but better drained than bogs. Water is clear, sometimes yellowish, with low to moderate dissolved mineral content (Polhemus et al., 1992). Upland marshes are dominated by hydrophytes

Upland swamps—Perennial to seasonally intermittent forested wetlands in upland areas (100–1200 m) with moderate to high rainfall. Water is non-acidic, with characteristics similar to those of upland marshes (Polhemus et al., 1992)

Lowland freshwater marshes—Generally, at low elevation, <100 m that is not immediately adjacent to the coastline. They are maintained either by stream inflows or by exposure of the natural water table. Salinity <0.5‰. Marshes located on windward sides of the islands are less saline than those on leeward sides because of higher rainfall. Perennial lowland wetlands lacking trees but with abundant emergent vegetation (Polhemus et al., 1992). This also includes playa lakes, shallow wetlands found in flat central basins with slopes of 0.2 m per km and where evaporation greatly exceeds inflow of water (Baker, 2016)

Lowland saline marshes and estuaries—Also called coastal wetlands, are areas with perennial, tidal, or seasonal brackish water, often resulting from underground saltwater intrusion (Polhemus et al., 1992). Estuaries are stream segments between the coastline and 1 m elevation (Parham and Lapp 2006 in Parham, 2008) that completely or partially enclosed water bodies typically found where sea mixes with fresh water from rivers and streams. They are maintained by perennial stream runoff and fresh water springs and their inland extent is determined by measurable tidal fluctuation and topography. The physical make-up of estuaries that represent the transition area between the inland waters and the sea can vary widely. The inland margins of bays, harbors, inlets, and lagoons can all be considered estuaries

Open water bodies

Ponds—A body of standing water usually smaller than a lake (Merriam-Webster, 2018). Water depth is shallow, allowing sun to reach the bottom of the water body (euphotic zone). Although shallow, ponds are often thermally stratified (change in temperature at different depths) and have abundant rooted and floating macrophytes (aquatic plants growing in or near water) (Horne and Goldman, 1994). Ponds can be ephemeral (only holding water at certain times of years)

Fresh and saline lakes—Fresh water lakes can be found at all elevations. While saline lakes are generally found near the shorelines. A lake is a body of water of natural origin with surface area >0.1 ha; maximum water depth >2 m, and the absence of a natural oceanic connection (Maciolek, 1982). Freshwater lakes have a salinity of <0.5‰ and saline lakes usually have a salinity >0.5‰ (Polhemus et al., 1992). Lowland freshwater lakes characteristically lacked a natural oceanic connection (surface or subsurface) of a magnitude sufficient to cause demonstrable tidal fluctuations. Saline lakes were usually, but not always, fed by seawater seepage and may have been diluted by rainwater, overland runoff, or groundwater, or concentrated by evaporation

Anchialine pools—A body of water with mixed salinity within a geological formation (coastal lava flows or limestone exposures) that exposes the underlying water table. They include typical small bodies of water as well as water in lava fields, tubes, cracks, and under rock overhangs, and open wells, and may occur singly or in groups (Maciolek and Brock, 1974). Pools display tidal dampening with some pools only having water at high tide. Water flows underground and the pools have no regular surface connection to the sea. Water chemistry is highly variable with salinities ranging from 0 to 41 parts per thousand and surface temperatures ranging from 17 to 36°C (Yamamoto et al., 2015).

Occur singly or in groups and vary in size and depth ranging from a 30 cm or less in surface area to multiple square m and from a couple of cm to over a 30 m in depth (Yamamoto et al., 2015). Depths are variable depending on tidal stage, with certain very shallow pools appearing only at high tide (Polhemus et al., 1992)

Artificial reservoirs—Any human-created body of water constructed depression that holds water with input usually from natural precipitation. Usually used for for agriculture (irrigation or milling operations), other socioeconomic purposes, or created by warfare (e.g., reservoirs, domestic water supply, bomb craters, wastewater treatment plants, stock ponds, aquaculture, golf course hazards) (Polhemus et al., 1992).

Stock ponds: Usually small bodies of water that do not require a boat to cross, are used for providing water to livestock across ranch lands and can be found on most of the main Hawaiian islands.

Settling ponds: Original settling ponds were created in conjunction with milling of sugar. Sugar milling required large volumes of water and many mills were located near wetlands, streams, or rivers. Continue to be built for different industries in Hawai'i.

Wastewater treatment plant: Usually open water impoundments with a polyurethane lining. With enough the buildup of sludge natural wetland vegetation and aquatic invertebrate composition can develop.

Golf course water features: Can vary in depth and size, may be aerated, and have shoreline vegetation

Ponds

Wetlands with vegetation dominated by 'aka'akai, kaluhā, and *Cyperus laevigatus* (makaloa) can be found bordering small spring-fed ponds in areas near the coast on the islands of Moloka'i, Maui, and Hawai'i. Water hyssop is prominent in very shallow water on the edges of these ponds and can exceed the coverage of the dominant sedges at some sites (Gagne and Cuddihy, 1999).

Fresh and Saline Lakes

Fresh and saline lakes occur at all elevations throughout the archipelago. In general, upland lakes are freshwater while those near the coastline are saline to hypersaline (Table 5).

Table 2 List of animal that can be found in Hawai'i wetlands.

Scientific	Hawaiian, English common	ESA listing status	Native, nonnative, or migratory
<i>Waterbirds</i>			
<i>Gallinula chloropus sandvicensis</i>	'Alae 'ula, Hawaiian Gallinule	E	Native
<i>Fulica alai</i>	'Alae ke'o ke'o, Hawaiian coot	E	Native
<i>Himantopus mexicanus knudseni</i>	Ae'o, Hawaiian stilt	E	Native
<i>Shorebirds</i>			
<i>Nycticorax nycticorax</i>	'Auku'u, Black-crowned night heron		Native
<i>Pluvialis fulva</i>	Kōlea, Pacific Golden Plover		Migratory
<i>Arenaria interpres</i>	'Akekeke, Ruddy turnstone		Migratory
<i>Calidris alba</i>	Hunakai, Sanderling		Migratory
<i>Heteroscelus incanus</i>	'Ulili, Wandering tattler		Migratory
<i>Numenius tahitensis</i>	Kioea, Bristled-thighed curlew		Migratory
<i>Waterfowl</i>			
<i>Branta sandvicensis</i>	Nēnē, Hawaiian goose	T	Native
<i>Anas wyvilliana</i>	Koloa, Hawaiian duck	E	Native
<i>Anas clypeata</i>	Koloa mohā, Northern shoveler		Migratory
<i>Anas acuta</i>	Koloa māpu, Northern pintail		Migratory
<i>Anas platyhynchos</i>	Mallard		Nonnative/migratory
<i>Aythya affinis</i>	Lesser scaup		Migratory
<i>Reptile</i>			
<i>Rana catesbeiana</i>	North American bullfrog		Nonnative
<i>Bufo marinus</i>	Cane toad		Nonnative
<i>Fish</i>			
<i>Stenogobius hawaiiensis</i>	'O'opu naniha		Native
<i>Eleotris sandwicensis</i>	'O'opu akupu or 'O'opu ōkuhe		Native
<i>Gambusia affinis</i>	Mosquito fish		Nonnative
<i>Poecilia reticulata</i>	Rainbow fish		Nonnative
<i>Limia vittata</i>	Cuban Molly		Nonnative
<i>Xiphophorus helleri</i>	Green swordtail		Nonnative
<i>Oreochromis mossambicus</i>	Mozambique tilapia		Nonnative
<i>Sarotherodon melanothron</i>	Black-chined tilapia		Nonnative
<i>Tilapia zillii</i>	Redbelly tilapia		Nonnative
<i>Pisodonophis cancrivorus</i>	Rice-paddy eel		Nonnative
<i>Misgurnus anguillicaudatus</i>	Dojo, or Oriental weatherfish		Nonnative
<i>Crustaceans</i>			
<i>Macrobrachium grandimanus</i>	'Ōpae 'oeha'a		Native
<i>Molluscs</i>			
<i>Neritina vespertina</i>	Hapawai		Native
<i>Theodoxus cariosus</i>	Pipiwai		Native
<i>Thiaridae</i> sp.	Malaysian live-bearing snails		Nonnative
<i>Pomacea</i> spp.	Apple snail		Nonnative
<i>Pomacea canaliculata</i>	Apple snail		Nonnative
<i>Pila conica</i>	Apple snail		Nonnative
<i>Corbicula fluminea</i>	Asiatic freshwater clam		Nonnative
<i>Insects</i>			
<i>Megalagrion</i> spp.			Native and nonnative
<i>Anax</i> spp.			Native and nonnative
<i>Nesogonia</i> spp.			Native and nonnative
<i>Pantala flavescens</i>	Globeskimmer		Nonnative
<i>Micracanthia humilis</i>			Nonnative
<i>Mesovelia mulsanti</i>	Water treader		Nonnative
<i>Saldula</i> spp.			Nonnative
<i>Microvelia vagans</i>	Waterbug		Nonnative
<i>Polypedilum nubiferum</i>	Spotted winged midge		Nonnative
<i>Aedes</i> spp.	Mosquito		Nonnative
<i>Culex</i> spp.	Mosquito		Nonnative
<i>Toxorhynchites</i> sp.	Mosquito		Nonnative
<i>Cricotopus bicinctus</i>			Native
<i>Ochthera circularis</i>			Nonnative
<i>Odontomyia ochropa</i>			Nonnative
<i>Chironomus esakii</i>	Large midge		Nonnative
<i>Coleoptera</i> spp.	Water beetle		Native and nonnative

Table 3 Bog sub-type on the main Hawaiian islands.

Island	Bog description/location
Hawai'i	Windward slopes of the Kohala Mountains, Mauna Kea, and Mauna Loa (Jacobi, 1990 in Cuddihy and Stone, 1990)
Hawai'i and Maui	Two bogs are believed to have formed in former small lakes, one along the Wailuku River, Hawai'i (Treeless bog), the other a subalpine bog on East Maui (Flat Top bog)
Maui	High-rainfall windward slopes of east Maui (Loope et al., 1991 in Cuddihy and Stone, 1990)
West Maui, Moloka'i, O'ahu, and Kaua'i	Very wet, poorly drained areas, near mountain summits (Selling, 1948 and Carlquist, 1980 in Cuddihy and Stone, 1990)
Kaua'i	A few sloping bogs also occurred on steeper terrain where precipitation was extremely high, such as in North Bog in the Wai'ale'ale summit region
Kaua'i	The one low-elevation bog on Kaua'i (Kanaele) occurs on shallow, poorly drained acidic peat (Cuddihy and Stone, 1990)

Table 4 Plants characteristically found in wetland sub-types.

Subtype	Characteristic plants
Bog	<i>Oreobolus furcatus</i> , <i>Carex</i> spp., <i>Rhynchospora</i> spp., <i>Dicanthelium</i> spp., <i>Dubautia</i> spp. [na'ena'e] and a diversity of unusual bog-tolerant plants such as <i>Argyroxiphium grayanum</i> (green swords), <i>Plantago</i> spp. (laukāhi), the daisy-like <i>Lagenophora viridis</i> , the fleshy-trunked lobelias of Maui and Kaua'i (<i>Lobelia gloria-montis</i> , <i>L. kauaensis</i> , <i>L. villosa</i>), and fragile clubmoss (<i>Selaginella deflexa</i>), and endemic violets (<i>Viola maviensis</i> , <i>V. chamissoniana</i> var. <i>robusta</i> , and others) (Cuddihy and Stone, 1990)
Upland Marsh	Hydrophytes—reeds and sedges, submerged or floating macrophytes, pondweeds and waterlilies
Upland Swamps	Trees, shrubs, and variety of aquatic macrophytes in open sunlit areas
Lowland freshwater marshes	See Lichvar et al. (2016)
Lowland saline marshes and estuaries	Shrubs and trees such as <i>Pritchardia</i> spp. (loulou), <i>Chamaesyce olowaluana</i> ('akoko), <i>Columbrina</i> spp. (kauila), and <i>Kanaloa kahoowawensis</i> (kanaloa) (Athens, 1997; Athens et al., 2002)

Table 5 Six lakes historically identified from the Hawaiian archipelago (Maciolek, 1982).

Lake name	Island	Elevation	Salinity level	Basin origin
Waiau	Hawai'i	3969 m—Alpine	Fresh	Glacier
Wai'e'ele	Maui	3040 m—High	Fresh	Volcanic (crater)
Nōmilu	Kaua'i	Sea level	Euhaline	Crater
Kauhakō	Moloka'i	Sea level	Saline	Volcanic (Crater)
Green (Wai a Pele) ^a	Hawai'i	Sea level	Fresh/Saline	Volcanic
Laysan	Kamole (Laysan)	Sea level	Hypersaline	Coraline

^aGreen Lake filled with lava on June 2, 2018.

Lake Waiau, an alpine lake formed during the post-Pleistocene melting of glaciers that once occurred on the summit of Mauna Ke'a (Massey, 1978). It is the shallowest freshwater lake at 3 m deep (Maciolek, 1982). Wentworth and Powers (1941) suggest that when frozen, water trapped by fine grained sediments creates an impermeable layer (Woodcock, 1980) keeping water from draining out of the basin, allowing the lake to persist.

Lake Kauhakō differs slightly from the other lakes. Formed during the late Pleistocene, it occupies a precipitous crater 250 m deep within the Kalaupapa peninsula (Stearns and Macdonald, 1947; Macdonald and Abbott, 1970). Unlike other lakes in Hawai'i, sea water intrudes from the basal water table, although there is no evidence of a connection to the ocean (Maciolek, 1982).

Lake Laysan (40 ha) is the only lake in the Hawaiian archipelago that does not occupy a basin primarily formed by volcanic origin. This shallow, central lake is 2.4 m above sea level and is perched on a layer of upraised nonporous coral on a secondarily raised atoll (Rauzon, 2001). This lake was fed by precipitation and washover by seawater. Due to continuous evaporation, the lake water is hypersaline, having a salinity approximately three times greater than the ocean (Schauinsland, 1899; Elschner, 1915; Warner, 1963; Caspers, 1981). Laysan Lake and the fresh seeps currently found along its shores and inland are thought to have been more numerous prior to human contact.

Anchialine Pools

Anchialine pools supported unique plants and animals and Hawai'i may have had the highest biological diversity of any such pools in the world (Maciolek, 1986). Crustaceans and mollusks were the most abundant animals in these ecosystems, although certain rare insects such as the damselfly *Megalagrion xanthomelas* were also present. Waterbird and shorebirds were also present in these ecosystems. Tiny, herbivorous shrimp or 'ōpae 'ula (*Halocaridina rubra*) were the most characteristic species. Algae and bacteria of different forms were present in anchialine pools and many served as food for aquatic animals. The indigenous aquatic vascular plant, tassel pondweed or widgeon grass (*Ruppia maritima*), was likely characteristic of leeward pools on the island of Hawai'i (Stone, 1989).

Historical Range

Estimations of pre-settlement wetlands range from 20,963 ha (USFWS, 1990) to 126,300 ha (van Rees and Reed, 2014). van Rees and Reed (2014) point out that the Hawai'i data included in the 1990 USFWS report (sometimes cited as Dahl, 1990) primarily relied upon a review letter (Kosaka, 1990, *in litt.*) that cited an old Hawai'i wetland assessment that no longer exists and the summary provided no information regarding sources of data or methods used. Kosaka's (1990) analysis started in 1780 while van Rees and Reed went back a 1000 years (plus or minus) to pre-human contact. It should be noted that the 1990 estimate was made before significant advances in Geographic Information Systems (GIS) and computer technology (van Rees and Reed, 2014).

There are no known wetland range estimates for the NWHI.

Viability

Ecosystems sustain through resiliency, redundancy, and representation. The viability of wetlands and open water bodies depends on maintaining multiple and distributed types (redundant) of sufficient quality and size (resilient) with species richness and genetic range (representative) to survive across its ecological environment over time. The phrase "ecologically healthy" refers to functions affecting biodiversity, productivity, biochemical cycles, and evolutionary processes that are linked to the climatic and geologic conditions in the region (Karr et al., 1986 and Karr, 1991 in Naiman et al., 1992). The ecologically healthy, or viable, wetlands that existed throughout the islands of Hawai'i prior to human contact likely maintained natural connections between system components. Native biota that was historically characteristic of Hawaiian wetlands filled environmental niches necessary to sustain the ecosystem.

Resilience is defined as the amount of disturbance that the system can absorb without a change in structure and composition (Holling, 1973; Carpenter et al., 2001). Disturbance in wetlands and water bodies include natural forces such as floods and droughts. Due to hydrogeomorphological characteristics (water easily replaced via rain/groundwater), early stages of succession (lack of trees, pioneer species easily replaced) and highly adapted flora and fauna (avian dispersal, floating seeds, and root systems), "healthy" wetland and water bodies have an increased capacity (high resiliency) to be able to recover from such stochastic and natural events.

Redundancy refers to the extent and range across a given landscape. Redundancy from having multiple resilient wetlands and water bodies can decrease the risk of loss. Wetland sub-types with few occurrences across the islands are less resilient to catastrophic events that might otherwise have a relatively minor impact on those that are widely-distributed (Stacey and Taper, 1992). Hawai'i has limited wetland resources due to its unique hydrogeomorphological characteristics. However, it can be assumed that there were more wetlands spread across the islands before humans arrived, resulting in a higher level of redundancy.

Although historical data are lacking, representation of wetlands and mid to low elevation water bodies in their historical state (pre-human contact) likely entailed a high level of diversity that was duplicated from unit to unit. Compared to lower elevation open water bodies and wetlands, high elevation open water bodies in their historical state likely maintained a lower level of floral and faunal diversity. It can be assumed that adaptation related to the high diversity of native wetland and water body biota that evolved specifically in the tropical environment increased the ability to persist.

The primary driving factor for maintaining a high level of representation for wetlands is related to dispersal and connectivity. Connectivity refers to the ability of plants and animals to move between habitat patches on the landscape (Hanski, 1998; Tischen-dorf and Fahrig, 2000). Wetland and open water body connectivity (both structural and biological) is a dynamic process involving wetting and drying cycles that result in a varied frequency of habitat patches being connected by water (Morris, 2012). Floods are particularly important for dispersal of vegetative propagules (plant structures such as fragmented runners or seeds) into streams, which may then be dispersed in floodwaters to distant sites. Buoyant propagules are usually dispersed farther than those that sink. Biological connectivity is maintained through dispersal and considers whether species can move to similar or other suitable habitat. Species mobility varies and results in different rates, patterns and scales of biological connectivity on the landscape (Taylor et al., 1993).

Wind, water, and birds are the most important natural dispersal vectors in aquatic systems. Wind-mediated seed dispersal is more effective in connecting wetlands that are close together and aligned with the direction of the prevailing winds (Morris,

Table 6 Levels of resiliency, redundancy, and representation for wetland and open water bodies that existed in the Hawaiian archipelago prior to human contact.

<i>Sub-type</i>	<i>Resiliency</i>	<i>Redundancy</i>	<i>Representation</i>
<i>Wetland</i>			
Upland Bogs, Marshes, and Swamps	High	Low	High
Lowland freshwater and saline marshes and estuaries	High	Medium	High
<i>Open water bodies</i>			
Fresh and saline lakes	High	Low	High
Anchialine pools	High	High	Low

2012). Waterbirds are capable of dispersing propagules and eggs of invertebrates that become attached to the feet, feathers or bill, or are consumed and survive passage through the gut. Aquatic invertebrates with wings can also disperse to and populate similar wetland habitats. Water moving between existing water bodies via surface or underground flow can also carry propagules, eggs, and flightless adult and larval forms of aquatic invertebrates.

Table 6, provides a summary of the viability of wetlands and open water bodies in their historical state. These values are assumed based on what is known about them in their native state. For instance bogs and lakes likely recovered quickly from storms and were well-represented via species and genetic diversity. However, there were relatively few bogs and lakes spread across the archipelago and therefore had low redundancy. In contrast, anchialine pools were fairly widespread and well-connected, but contained less biological diversity and thus had lower representation.

Change From Historical Condition

Around 800 AD Polynesians first colonized the Hawaiian islands (Vitousek et al., 2004) and altered wetlands and open water bodies that could be best used for agriculture and fishing (Armstrong, 1983). Despite these habitat modifications by early Hawaiians, many areas of extensive wetlands remained intact and were still utilized by the native fauna (USFWS, 2011).

Fishponds were built to control water flow for the purposes of growing and harvesting fishes, algae, crabs, and shrimp (Table 7). Over 350 fishponds of various kinds have been identified on the eight major Islands. (Apple and Kikuchi, 1977 in Stone, 1989). Fishponds were apparently not developed by other pre-contact cultures of the Pacific but were used especially from the 14th to 19th centuries in Hawai'i (Kikuchi, 1976). At the peak of the pre-European contact era, in approximately 1600 AD, almost all sizable saline and brackish water bodies in the main Hawaiian islands were being used as fishponds (Kikuchi, 1976).

Many low-to-mid elevation freshwater wetlands, upslope from these fishponds, were used for agricultural production of *Colocasia esculenta* (kalo, taro). Valeros and O'Neil (2019) describes the Hawaiian irrigated farming systems which started around the 15th century. Forests above these wetlands such as Kawai Nui Marsh and Kahana Bay (island of O'ahu), Hanalei Valley (island of Kaua'i), and Waipi'o Valley (island of Hawai'i) may have been removed partly to encourage erosion of upland soils into lowland wetland areas used for kalo cultivation (Spriggs, 1985; Stone, 1989). By 1778, kalo was cultivated in nearly every valley in the main Hawaiian islands that contained a stream (Handy and Handy, 1972; Kirch, 1982). As such, it has been proposed that Polynesians actually increased the extent of wetland ecotype in the islands (Stone, 1989). Some of these sites, such as Ke'anae (island of Maui) and Waipi'o (island of Hawai'i), still cultivate kalo today.

The arrival of Westerners starting with British Captain James Cook's expedition in 1778 triggered drastic changes for the Hawaiian culture. Around 1835, plantation sugarcane cultivation led to more extensive stream diversions by transferring large volumes of water out of natural watercourses and into complex systems of ditches, tunnels, flumes, and reservoirs (Wilcox, 1996). The last sugar mill closed in 2016 on the island of Maui (Keany, 2016).

Table 7 Types of Hawaiian fishponds (Kikuchi, 1976).

<i>Fishpond type</i>	<i>Description</i>
Shore ponds or salt water ponds (<i>loko kuapa</i> and <i>loko 'umeiki</i>)	Kuapa were made either by extending a semicircular wall from the shore into the sea and hack to shore, or by walling off the narrowest part of an entrance to a small bay or inlet. <i>Loko 'umeiki</i> were "surrounded by a low wall that is submerged at high tide and has openings walled on each side like lanes, leading in or out of the pond."
Inland ponds or brackish and freshwater ponds were divided into three categories: <i>loko pu'uone</i> (not fresh water), <i>loko i'a kalo</i> , and <i>loko wai</i> (fresh water)	<i>Loko pu'uone</i> were usually connected to the sea by a ditch or stream. <i>Loko i'a kalo</i> were the "taro fish ponds," and <i>loko wai</i> were natural ponds (Summers, 1964 in Stone, 1989)

During this time, many kalo lo'i were converted to rice paddies as a result of a predominately Asian plantation workforce. In 1899, Hawai'i was the third-largest producer of rice in the United States. In 1907, rice plantings covered 3804 watery hectares and produced 42 million pounds of rice. By 1930 most of the Hawaiian fishponds and kalo lo'i had been abandoned (Kikuchi, 1976), drained and filled for dryland agriculture (Stone, 1989; Meier et al., 1993). The last rice mill in Hawai'i, Haraguchi Mill, closed in 1960 (Adams, 2005).

Starting in the early 1900s, the most extensive lowland wetland and open water body subtypes, such as fresh and saline marshes (USFWS, 2010) (Table 8) along the coast were filled or otherwise modified. Areas such as Wai Momi "Waters of Pearl, Pearl Harbor" (island of O'ahu) is said to have had the most fishponds along its shores throughout the State before development in the early 1900s began of what is now Joint Base Pearl Harbor-Hickam (NPS, 2019). In the early 1900s, Waikiki was still a vast lowland marshland encompassing >809 ha which was used for kalo lo'i, fishponds, rice paddies, and duck ponds (Young, 2013). By 1920, Waikiki was drained and filled with dredge material from the Ala Wai Drainage Canal creating dry land for today's Waikiki.

Rapid population growth and urban development after World War II resulted in additional demands for water and land (van Rees and Reed, 2014; Stone, 1989).

A significant amount of what were previously wetlands across the State are now occupied by hotels, housing developments, golf courses, shopping centers, landfills, military installations, highways, former sugarcane fields and settling ponds, and industrial sites.

Lowland wetlands and open water body subtypes have also been hydrologically altered to control flooding in urban areas. Modifications such as stream channelization redirect flow and prohibits this water source from infiltrating lower-elevation wetland and open water body subtypes. Lowland wetlands subtypes are among the most vegetatively degraded of all wetlands habitat types. A few small areas still persist and mostly consist of invasive *Brachiaria mutica* (California grass) and a few patches of native *Schoenoplectus californicus* (kaluhā or bulrush). Kawai Nui is the State's largest remaining marsh (336 ha).

Nonnative mammals have greatly impacted the native vegetation in wetland and open water body subtypes. The first introductions of nonnative mammals arrived with Polynesians around 400 A.D consisting of pigs (*Sus scrofa*), dogs (*Canis familiaris*), and rats (*Rattus* spp.) (Kirch, 1982). The Cook expedition and subsequent explorers traveled with livestock such as pigs, goats, and cattle to serve as food sources for seagoing explorers (Tomich, 1986; Loope, 1998). They were also offerings to Hawaiian Royalty. The mild climate of the islands, combined with the lack of competitors or predators including hunting restrictions by Hawaiian law, led to the successful establishment of large populations of these invasive mammals, to the detriment of all native Hawaiian species and their habitats.

Lake Laysan has varied in depth over the last century. Impacts of guano mining starting in 1891 and extreme defoliation of the island by rabbits released in 1903 caused drifting sand to fill in portions of the hypersaline lake and its proximal freshwater seeps (Ely and Clapp, 1973). In the 1860s, the lake was at most 9.1 m deep, but by the 1920 it averaged 0.91–1.52 m deep, because of the buildup of sand that had been blown in by sand storms (Rauzon, 2001). Professor William Alanson Bryan estimated 10 million seabirds on Laysan in 1903, but 8 years later, the estimation was at little more than a million. In those 8 years, the Pritchardia palms, unique to Laysan, and the island's *Santalum ellipticum* (sandalwood trees) both became extinct. By 1918, the rabbits had eaten so much that the remaining vegetation was only enough to sustain 100 rabbits. Twenty-six plant species had been eradicated, and the Laysan millerbird (*Acrocephalus familiaris familiaris*) gone extinct (Rauzon, 2001).

The USFWS has been working towards eliminating invasive species on the island of Laysan. The vegetation including native bunchgrass has rebounded and native sedges grow thick around the lake's edge. The island is now home to 15 species of endemic insects, the Laysan duck (*Anas laysanensis*), the rarest duck in the world (Liittschwager and Middleton, 2005), the Laysan finch (*Telespiza cantans*), the Laysan millerbird (since translocated by USFWS in 2011 and 2012), and 18 other bird species that nest here and use Lake Laysan, the only lake in the NWHI. Once extirpated from Laysan, many native plant species, such as *Eragrostis variabilis* (kawelu or lovegrass), were reintroduced from other leeward islands (Liittschwager and Middleton, 2005).

Due to their upland, remote locations, montane bogs, upland marshes and swamps have maintained a relatively intact native vegetation community. Being more abundant than bogs, some upland marshes and swamps are transitioning from a native to a nonnative dominated vegetation community (Table 9). Lowland saline marshes are now represented by a rather thickly-growing, species-poor plant community, dominated by *Batis maritima* (pickleweed) and occur in muddy lowland wetland and open water body subtypes periodically flooded by saltwater. Pickleweed was first reported in the Hawaiian islands in 1859 by Hill-ebbrand (1888) and has since spread widely, likely displacing native communities (Gagne and Cuddihy, 1999). Examples occur at Kealia and Kanahā ponds on Maui.

Due to the remote location of Wai'ele'ele and Kauhakō, the terrestrial flora and fauna around the lakes and the aquatic flora and fauna inside the lakes have maintained a relatively intact native community. Although remote, changes at these lakes are being studied and monitored at Lake Waiau by U.S. Geological Survey and Lake Kauhako (cycling process) by NPS. Nōmilu, near the

Table 8 Examples of lowland freshwater marshes in the Hawaiian islands.

Island	Place names
Hawai'i	Pololū, Waimanu, and Waipi'o valleys
O'ahu	Kawai Nui, He'eia, (including Ki'i, Punamanō, and Punaho'olapa), and 'Uko'a Marsh
Kaua'i	Hanalei and Mānā

Table 9 Upland swamps in the Hawaiian islands (Polhemus, 2015).

Location	Description of upland swamp
Windward Mauna Kea, Hawai'i	This area contains closed canopy forest, with a sphagnum moss understory. Some areas have been degraded by cattle grazing, leading to development of artificial upland marsh zones dominated by introduced grasses
Pu'u o Umi, Hawai'i	Located at the summit area of the Kohala Mountains, this swamp exists at a lower elevation than is typical for such ecosystems in Hawai'i
Windward Haleakalā (uluhe swamp), Maui	This is a large area of discontinuous hydric soils thickly overgrown by <i>Dicraopteris linearis</i> (uluhe fern) and scattered with 'ōhi'a and <i>Acacia koa</i> (koa)
Mt. Ka'ala, O'ahu	The flat summit of Mt. Ka'ala supports a swamp formation dominated by low stature 'ōhi'a and <i>Cheirodendron trigynum</i> ('olapa). The largest dragonfly species in the United States, pinao, (<i>Anax strenuus</i> var. <i>kaenana</i>), and several species of native tree snails can also be found here
Ka'au Crater, O'ahu	Appears to have once held a lake that has subsequently been disturbed by human activity and weed invasion. The currently dominated by the indigenous sedge, <i>Cladium jamaicense</i> ('uki), mixed with <i>Schoenoplectus lacustris</i> ('aka'akai), and <i>Commelina diffusa</i> (honohono) and has no open water (Gagne and Cuddihy, 1999; Polhemus, 2015)
Alaka'i Swamp, Kaua'i	The Alaka'i Plateau in the central interior of Kaua'i contains an extensive upland swamp at elevations ranging from 1288 to 1585 m. Rainfall on the plateau is in excess of 5000 mm per year (one of the wettest spots on earth) (Giambelluca et al., 2013), and accumulates in various irregularities amid the terrain and in pockets at the bases of tree roots. The Alaka'i Swamp suffered a significant loss of canopy cover during Hurricane Iniki in 1992, and has only partially recovered. The opening of the canopy has allowed a certain amount of drying to occur, and there seems to be a general consensus among researchers familiar with the area that the overall character is not as wet and saturated as previously. Some classify the swamp as a montane wet forest containing extensive shallow bogs

seashore, shares similar terrestrial plant composition from transition from a native to a nonnative community as lowland fresh and saline marshes and estuaries.

Other currently known open water bodies that are not considered a lake by definition includes: Halulu Lake on the island of Ni'ihau; Violet Lake, Wai'anapanapa, and Kanahā Pond on the island of Maui; Meyer Lake on the island of Moloka'i; and Waiakea Pond and 'Aimakapā on the island of Hawai'i (Maciolek, 1982). All of these have features that are considered to represent wetland subtypes (Table 1).

There are currently an estimated 700 or so anchialine pools found throughout the archipelago, although they are most abundant on the islands of Hawai'i and Maui (Yamamoto et al., 2015). Prior to arrival of Westerners, Hawaiians used anchialine pools as potable water sources, bathing pools, and fishponds. As a result, many of the anchialine pools show evidence of cultural modification, by either Polynesians or modern humans (Maciolek and Brock, 1974). Anchialine pools throughout the State of Hawai'i have steadily become susceptible to degradation from human-induced factors. A majority of these pools have become ecologically degraded and their native biota drastically altered from its pristine conditions (Brock, 1985). Approximately one-third of the anchialine pools in the district of South Kohala on the island of Hawai'i have been destroyed by hotel development (Stone, 1989).

Artificial reservoirs often duplicate the processes and function occurring in natural wetlands and can be complex systems in which water, plants, animals, microorganisms and the environment (sun, soil and air) interact. These bodies of water can attract plant growth and wildlife while also being used for recreational purposes such as boating and fishing. Reservoirs in Hawai'i are usually created by damming the downstream end of a drainage basin. These dams and reservoirs frequently interrupt normal sediment transport processes in rivers and stream systems and affect water temperature and quality (i.e., dissolved oxygen, acidity, salinity, turbidity, temperature). Transport and assimilation of nutrients, amount of in-stream organic matter and related decomposition, channel morphology, habitat quality for native aquatic species, and riparian vegetation recruitment and survival are also affected. Water quality can range from good to poor, with water levels ranging from stable to fluctuation. In Hawai'i, the first reservoirs were constructed on sugar plantations for irrigation and domestic uses by plantation workers. Reservoirs are still used today in Hawai'i for many different purposes (Table 10).

Current Extent and Range

The last comprehensive wetland inventory for all of the islands in the State of Hawai'i was completed in 1979 by the USFWS (Cowardin et al., 1979). To this day, there is no completely accurate map available for Hawai'i's wetlands although various attempts have been made.

Kosaka (1990 *in litt.*) and van Rees and Reed (2014) have made estimates to determine the amount of wetland and open water bodies that have been lost from pre-Polynesian contact and the mid 1900s. These studies indicate the highest wetland loss occurring in the lowland wetland subtypes (at or below approximately 300 m elevation) with majority of it occurring on O'ahu.

Table 10 Use of artificial reservoirs in the Hawaiian islands.

<i>Artificial reservoirs</i>	<i>Impacts</i>
Stockponds	As the number of ranches decreased over the years and agriculturally zoned land changed over to urban zoning, it can be assumed that a number of these stock ponds have been drained and filled in for development. Such ponds often provide habitat for non-native aquatic insect species
Settling ponds (agriculture)	Prior to releasing the “used” water, it was sent to settling ponds before being discharged. The ponds at James Campbell National Wildlife Refuge (NWR) sit on a former wetland that was converted to settling ponds. Today, James Campbell NWR manages these settling ponds to assist in the recovery of threatened and endangered waterbirds and provide protected habitat for migratory shorebirds and waterfowl
Wastewater treatment ponds	May not provided similar vegetative composition and density to other wetlands as a result of a polyurethane lining. However, with the buildup of enough sludge material and algae, aquatic plants can become established
Golf course water feature	If the golf course is near a stream or wetland, water features can flow directly into the stream or wetland carrying high nutrient loads and other contaminants. Even so, certain golf course water features, such as those in upland Lanai, can provide documented habitat for rare native damselfly species
Cultivation of aquatic foods	This started Hawai'i started with the native Hawaiians for kalo loi and fish ponds. Since then, food harvest has expanded to include taro, rice, lotus, prawns, shrimp, and other fish species. Many of these fields/ponds were in or near the outskirts of urban areas. The majority of these wetlands occur on O'ahu, particularly in the area near Kahuku. The industry reached its peak in the mid-1980s, then declined, but is currently increasing again in volume (Mencher, <i>in litt.</i> 2005)
Bomb crater	Sailor's Hat is an artificially created anchialine pool on the south coast of the island of Kaho'olawe. In 1965, the Navy bombed the area and it left a crater 50 m in diameter with a 5-m-deep pool at the bottom (Brock and Bailey-Brock, 1998)

Reeves and Amidon (2018a,b) looked at present distribution of the following wetland subtypes: bogs, upland marshes and swamps, lowland fresh water and saline marshes, estuarine, and open (fresh and saline) water inland of the sea shoreline in the main Hawaiian islands (Figs. 1–4 and Table 11).

The largest wetlands lost over the past century were on O'ahu and include: Waikīkī, Pearl Harbor, Ka'elepulu (now Enchanted Lake), and Ālia pa'akai (Salt Lake). The 1.2 ha Ka'elepulu Wetland Preserve is a small, privately-owned, preserve set aside in 1955, is a remnant of the once expansive Ka'elepulu wetland. The Mānā Plains on Kaua'i, once the largest wetland in Hawai'i at over 650 ha (c. 1910), was reduced to only 80 ha by 2006 primarily due to water diversions for sugarcane (Shallenberger, 1977; Erickson and Puttock, 2006). Within these last 80 ha, 14 ha are designated the Mānā Plain Forest Reserve (formerly the Kawai'ele Waterbird Sanctuary). The greater Mānā Plains area is also an important wetland area due to remaining scattered ephemeral (temporary) wetlands and a Navy wastewater treatment facility (Nadig, 2017, pers. comm.).

Four hundred-year-old Green Lake, located at the bottom of a crater in the Kapoho area on the island of Hawai'i, was considered the largest freshwater lake in Hawai'i (Macdonald and Abbott, 1970). On June 2, 2018, volcanic activity along the East Rift Zone of the active Kilauea volcano fed a channelized lava flow that entered Green Lake, boiling and evaporating the water. Within 5 h of lava entering Green Lake, lava filled the lake and no water remained (USGS, 2018).

Stressors

In the Hawaiian archipelago, wetlands and open water bodies experience a multitude of stressors including those related to human presence and abundance, and climate (Table 12).

Development and Altered Hydrology

Alterations in ground and or surface water due to development (residential, commercial, agricultural, and military) has resulted in wetland subtype losses. In Hawai'i, this ranges from water diversions, discharging fill, building dams, channelizing, pumping, grubbing, grading, deep ripping, and other agricultural or military land use practices (Erickson and Puttock, 2006). Urbanization of many of Hawai'i's lowland wetland subtypes occurring in coastal areas are highly valued for development, especially on the islands of O'ahu and Maui, but is increasing on all islands (Kane, 2014).

The primary demand for surface water over the past two centuries has changed overtime from agricultural to commercial and residential usage. The Hawai'i streams manuscript has a more extension write up on the impacts to surface flow.

The depletion of freshwater aquifers causes saltwater intrusion into coastal groundwater, altering the salinity levels in associated wetlands subtypes and thus decreasing the amount of available fresh or brackish water. Fluctuations in salinity levels alter the species composition of the vegetation and arthropod communities (M. Silbernagel, pers. com. 2008; [USFWS, 2011](#)).

Surface water is the primary source of water input for many wetland ecotypes, especially in the lowlands. Decrease in surface flow resulting from development can affect the succession rate of a wetland along with changes in the in species compositions. Surface water input from developed areas are also a source of water pollution. Further discussion on surface water can be found in the Hawai'i streams manuscript.

Recreation and Human Access

Due to their remote nature and steep terrain, many of the naturally formed wetlands and open water bodies at higher elevations in Hawai'i are spared from the heavy human access and recreation pressure that those in the lowlands are exposed to. This is likely a contributing factor in the preservation of native-dominated wetland ecosystems. By contrast, most lowland wetlands and open water bodies are significantly impacted by human recreation due to their proximity to urban areas. Natural and artificial lowland wetland and open waterbody subtypes are often used by off-road vehicles and dirt bikes, water sources for domesticated ungulates, golf courses, fishing, and boating. Anchialine pools are often used for bathing, lavatories, and dumping trash.

Water Pollution

The input of pollutants, such as fertilizer, human sewage, animal waste, pesticides and heavy metals can exceed the wetland's natural ability to absorb such pollutants and cause degradation as well as kill invertebrates, fish, birds and mammals. Lowland open water body ecotypes, susceptible to act as sinks for pollutants, which means that pollutants tend to accumulate and potentially increase the toxicity with time. Pollutants can enter the surface and groundwater water through urban and agricultural runoff, air pollution, leakage from landfills and dumps, and boats stirring up pollutants. Urban encroachment has the potential to negatively affect wetlands via flushing of household and industrial products into water-collecting systems (storm drains and roadside ditches) which lead to streams, wetlands, and the ocean. Currently, little is done to survey for toxicants in wetlands except for certain Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) sites on military bases.

Invasive Animals and Plants

Lowland wetland and many open water bodies ecotypes are mainly dominated by invasive fish which are suspected of degrading the food web by depleting the invertebrate prey base used by native birds ([Wirwa, 2007](#)). Invasive fish are especially problematic for anchialine pools where their waste products plug up water flow preventing proper functioning resulting in the loss of the pool as habitat (Wada, *in litt.* 2018).

Beyond the direct effects of trampling and consuming native plants, feral ungulates contribute significantly to severe erosion of watersheds, increased sediment levels in aquatic systems, and their behavior (i.e., rooting, moving across large expanses) facilitates the spread and establishment of competing, invasive plant species ([Merlin and Juvik, 1992](#)). Bogs are exceptionally vulnerable to destructive root and trampling by feral pigs because of soft, easily dug soils and the succulent plants they contain ([Stone and Stone, 1989](#)). Feral animals also remove riparian plant cover that provide shade, change temperature and light conditions which animals have adapted to, and increase nutrients and soil in water, effectively degrading or destroying habitat for aquatic wildlife ([Stone, 1989](#); [USFWS, 2011](#)).

In 2009, Bantilan-Smith et al. found the composition of plant communities of all wetland types in Hawai'i to be predominantly invasive. Invasive plants outcompete native species and eliminate open water, or shallows ([Griffin et al., 1989](#); [Henry, 2006](#)). The alteration of wetland plant communities due to extensive, blanketing overgrowth of invasive plants can greatly reduce the usefulness of wetland native fauna ([Morin, 1998](#); [Jenkins, 2016, in litt.](#)). *Juncus* species (rush, bog rush) such as *J. effusus* (Japanese mat rush), *J. ensifolius*, and *J. planifolius* are a threat to upland wetland subtypes.

Hawaiian introductions to lowland wetland subtypes included *Hibiscus tiliaceus* (hau), *Thespesia populnea* (milo), *Cocos nucifera* (coconut), and *Ludwigia octovalvis* (primrose willow) ([Athens, 1997](#)). Recent introductions and most frequently observed invasive species include: the non-native pickleweed, *Urochloa* (California grass), *Eichornia crassipes* (water hyacinth), *Pluchea indica* (Indian fleabane), seashore paspalum, and several mangrove species. Invasive grasses such as California grass is found in wet fields, ditches, and gullies between sea level and 700 m. It forms dense monotypic stands by layering from trailing stems. It will overgrow most shrubs and trees in its vicinity.

Mangroves are a group of trees or shrubs that live in the coastal intertidal zone. Five species were introduced to Hawai'i in the early 1900s for the purpose of stabilizing coastal mudflats. *Rhizophora mangle* (American mangrove), *Bruguiera gymnorhiza* (Oriental mangrove), and *Conocarpus erectus* (Silver-leaved Buttonwood) and are now established on nearly all of the major islands ([Allen, 1998](#)). Though considered beneficial in many parts of the world, mangroves have a deleterious effect to wetlands in Hawai'i by forming dense monotypic groves. Many of the anchialine pools along the Kona Coast are overgrown with invasive plants. Humans have brought many plant and invertebrate species to Laysan and other NWHI, notably *Cenchrus echinatus*, an invasive sandbur grass, and ants (family Formicidae).

Fig. 1 Representation of wetland and open water body area on the Island of Hawai'i.

Sea Level Rise, Groundwater and Marine Inundation and Flooding

According to global climate models developed by the Intergovernmental Panel on Climate Change, Sea Level Rise (SLR) is occurring globally and is expected to continue into the future. SLR is not expected to be uniform throughout the world, due to factors including, but not limited to (1) variations in oceanographic factors such as circulation patterns; (2) changes in Earth's gravitational field and rotation, and the flexure of the crust and upper mantle, due to melting of land-based ice; and (3) vertical land movement due to glacial isostatic adjustments, sedimentation compaction, groundwater and fossil fuel withdrawals, and other non-climatic factors (Spada et al., 2013 in Kane, 2014; National Oceanic and Atmospheric Administration, 2017). Further, SLR in Hawai'i will not be uniform across the islands due, in part, to vertical land motion resulting from the active growth of the island of Hawai'i (Caccamise et al., 2005 in Kane, 2014; Polhemus, 2015), causing that end of the island chain to become heavier and pushing land below sea level.

Hawai'i's wetlands and a few open water body subtypes, are found just inland of a narrow coastal barrier, are dependent upon ground and marine water sources to maintain water levels and are therefore impacted by SLR in several ways. The size, shape and location of these coastal wetland and open water body subtypes are expected to be modified due to increased flooding inundation. Water chemistry and salinization levels would change due to increased frequency of marine flooding and inundation during storms and high tides. There are several reports that discuss the imminent flooding and inundation of coastal wetlands in Hawai'i due strictly to SLR (Rotzoll and Fletcher, 2012; Kane, 2014; Htun et al., 2016).

The primary source of inundation for lowland wetland subtypes is expected to be from groundwater (Rotzoll and Fletcher, 2012). Rotzoll and Fletcher (2012) define groundwater inundation as "the localized coastal-plain flooding due to the rise of the groundwater table with sea level." As sea level rises, the water table will rise simultaneously, eventually rising above the land surface,

Fig. 2 Representation of wetland and open water body area on the Island of Moloka'i, Lāna'i, Maui, Kaho'olawe.

Fig. 3 Representation of wetland and open water body area on the Island of O'ahu.

creating new wetlands, and expanding others, subsequently changing surface drainage, saturate the soil, and inundate land in lower lying areas (Rotzoll and Fletcher, 2012). Groundwater flooding is a faster rate of inundation associated with a sudden rise in the watertable usually as a result of high precipitation rates.

Marine flooding and inundation will constitute a second source of coastal flooding (Kane and Fletcher, 2013). This coastal-plain flooding and inundation is expected to be caused by storm surge (wind driven) and marine overwash (wave driven) resulting from SLR and increases in tropical storm frequency and intensity (Fletcher et al., 1995). This wave action can change coastal

Fig. 4 Representation of wetland and open water body area on the Island of Ni'ihau and Kaua'i.

Table 11 Current distribution of wetland and open water bodies in the main Hawaiian islands (Reeves and Amidon, 2018a,b).

Island	Hectares	Percent of island	Percent of main Hawaiian islands
Hawai'i	478	<1	<1
Maui	736	<1	<1
Lāna'i	18	<1	<1
Moloka'i	468	1	<1
O'ahu	1269	1	<1
Kaua'i	788	1	<1

geomorphology, increasing the flooding risks of the coastal flood-plain (Bernard et al., 2011; Theuerkauf et al., 2014; Lentz et al., 2016, in Sweet et al., 2017).

Once SLR increases beyond 0.74 m, marine inundation will be the dominant source of coastal flooding (Kane and Fletcher, 2013; Polhemus, 2015). Results from recent studies in the main Hawaiian islands suggest estimates on impacts due to SLR have not adequately taken into account the effects of increased frequency and intensity of storm surge and marine overwash which have been grossly underestimated (Storlazzi et al., 2018; Vitousek et al., 2017). In addition to SLR, the islands are projected to experience more severe annual marine overwash flooding events. Increasing SLR, wave intensity, and flooding will continue to contribute significantly coastal erosion increasing the vulnerability of low-lying wetlands to morphological and chemical changes as coastal barriers are eroded. According to a study of the three most populated islands (Maui, O'ahu, and Kaua'i), approximately 70% of all sandy shorelines are chronically eroding (Fletcher et al., 2013).

Some of the most vulnerable lowland wetlands in Hawai'i have no sand dunes or very narrow and low sand dunes, such as Pala'au, south shore on the island of Moloka'i and Keālia National Wildlife Refuge on the island of Maui. Marine inundation is expected to overtake the impacts of groundwater inundation around 2040 (Kane and Fletcher, 2013; L. Jenkins *in litt.* 2016). The critical elevation at Keālia NWR (Maui) at which SLR impacts will rapidly accelerate is 0.2 m and is predicted to be exceeded by year 2028 ± 25. Other lowland wetlands are predicted to experience accelerated inundation at 0.6 m by year 2066 ± 16 (Kānaha State Wildlife Sanctuary on Maui and James Campbell NWR on O'ahu) (Kane, 2014).

Urbanization directly adjacent to coastal wetlands, or surrounding wetlands as is the situation at Kānaha Pond State Wildlife Sanctuary, will limit or prohibit coastal wetlands from a natural landward migration (Clausen and Clausen, 2014 in Kane,

Table 12 Primary stressors affecting wetland and open water bodies.

<i>Human presence/abundance</i>	<i>Climate</i>
Development and altered hydrology	Sea level rise, groundwater and marine inundation and flooding
Recreation and human access	Storms
Water pollution	Drought and increasing air temperature
Invasive animals and plants	

2014). In addition, any managed wetland ecotype near the coast will need to consider the impacts of flooding to surrounding communities and infrastructure such as bordering roads and sewage treatment facilities (Kane, 2014).

Other coastal water bodies, such as anchialine pools, are highly susceptible to the same climate impacts affecting lowland wetland subtypes with no significant barrier from the ocean. Anchialine pools have become tide pools and new pools have been created further inland at Manuka Natural Area Reserve on the island of Hawai'i over the past several years.

Storms and Tsunami

Increased frequency and intensity of tropical storms and hurricanes can impact wetlands and water bodies across all elevations. Tsunamis can impact all ecosystems that occur below the highest recorded runup height, which is currently 122 cm, and potentially higher. A tsunami in 2011 scoured some areas down to bare ground, but large areas of native and nonnative plants also survived the initial onslaught at Kanahā Pond on Maui. Salt water inundation can kill any salt-intolerant plants that survive the initial wave (F. and K. Starr, USGS, pers. comm. 2011).

Drought and Increasing Temperatures

Drought may affect aquatic systems through reduced streamflow, evaporation of standing water, increased water temperature, and the loss of native riparian and wetland plants (Still et al., 1999; Benning et al., 2002). Data on precipitation in Hawai'i, shows a steady and significant decline of about 15% over the last 15–20 years (Diaz et al., 2005; Chu and Chen, 2005). Increased air temperatures will also likely contribute to increased water temperatures. Shifts in vegetative composition, increased risk of forest encroachment, accelerated decomposition rates, and altered peat accumulation are all potential impacts to wetland and open water bodies due to increased temperatures.

Conservation Efforts

In general, the “protection” and active management of invasive species and water resources in wetlands and open water body subtypes are primarily for the management of wildlife conservation, flood control, and protection and usage of cultural sites. This is accomplished through cooperative efforts of State and Federal agencies, watershed partnerships, private organizations, and individual landowners and passive/social management through policies, laws, and other land protection. Wetlands identified as “protected” are those considered secure from development.

Starting in the mid 1900s, lowland wetland and open waterbody subtypes were being protected for the conservation of Hawaiian waterbirds (USFWS, 2011). Conservation and protection involves not only buffering wetlands from direct human pressures, but also maintaining important natural processes that operate on wetlands from outside, which may be altered by human activities. In many cases, active management also does not fully restore or reestablish a wetland to pre-disturbance functions and related physical, chemical and biological characteristics. Management can include invasive (plants and animals) species control or removal and manipulation of water resources to maximize vegetative and open water habitat for different life stages of waterbirds.

Wetlands such as Kawai Nui marsh are recognized by the State as a flood control basin whose water holding capacity continues to decrease as sediments from urban runoff are deposited in the marsh and associated waterways (House Bill 1218 (2017)). Hawaiian renaissance has contributed to an increase in revitalizing old kalo lo'i and fishponds for community and commercial usage. Kaloko-Honokohau National Historical Park is currently undergoing intensive restoration of 16 ha at 'Aimakapā Fish Pond including wetland vegetation (NPS, 2015).

The Wetlands Reserve Program may be one of a few activities to specifically protect, restore, and enhance wetlands. Originally authorized under the 1990 Farm Bill, it was later replaced by the Agricultural Conservation Easement Program in 2014.

Laws and Regulations

Several Federal and State Laws and regulations are in place to protect wetland and open water bodies (Table 13).

Table 13 Federal and State Laws and Regulations impacting wetlands and open water bodies.

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
Executive Order 1019	1909	Federal	Bird Reserve designation for protection in the NWHI except for Midway (which was under U.S. military jurisdiction)
Presidential Proclamation 2416	1940	Federal	Creation of Hawaiian Islands National Wildlife Refuge
Clean Water Act	1972	Federal	Establishes the basic structure for regulating discharges of pollutants into the waters of the United States and regulating quality standards for surface waters
Endangered Species Act	1973	Federal (USFWS and NMFS)	Protects critically imperiled species and their habitats from extinction
50 CFR 16	1974	Federal	Implements the Lacey Act (18 USC 42), which prohibits importation of injurious species
Convention on International Trade in Endangered Species	1975	International	Ensures that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild
Executive Order 11987	1977	Federal	Charges Executive agencies with restricting the introduction of exotic species into the natural ecosystems on federal lands; and encourages States to do the same
Executive Order 11988	1977	Federal	Requires federal agencies to avoid to the extent possible the long and short-term adverse impacts associated with the occupancy and modification of flood plains and to avoid direct and indirect support of floodplain development wherever there is a practicable alternative
Hawaii Administrative Rules, Title 4, Subtitle 6, Chapters 68 and 70	1981	Hawaii (Department of Agriculture)	Rules/amendments for noxious weeds, plant and non-domestic animal quarantine, plant import, and bromeliad import
Executive Order 13022	1996	Federal	Creation of Midway Atoll National Wildlife Refuge
Executive Order 13112	1999	Federal	Requires that a Council of Departments dealing with invasive species be created to prevent the introduction of invasive species and provide for their control and to minimize the economic, ecological, and human health impacts that invasive species cause
HRS 194-2	2002	Hawaii (Department of Land and Natural Resources)	Establishes Hawaii Invasive Species Council (HISC)
Act 85	2003	Hawaii (HISC)	Conveys statutory authority to HISC to continue to coordinate approaches among the various State and Federal initiatives for the prevention and control of invasive species
HRS Chapter 205A for Coastal Zone Management	2006	Hawaii (DLNR)	To preserve, protect, and where possible, to restore the natural resources of the coastal zone of Hawaii
Presidential Proclamation 8112	2006	Federal	Creation of Papahānaumokuākea Marine National Monument. Designated a World Heritage site in 2010
Act 36 (2011) HRS 150A-5.3	2011	Hawaii (DOA)	Imposes a fee for the inspection, quarantine, and eradication of invasive species contained in any freight brought into the State
HB 1568	2011	Hawaii (DOA)	Requires commercial harbors and airports in Hawai'i to provide biosecurity and to facilitate cargo inspections
HRS 174C Hawaii State Water Code	2013	Hawaii (CWRM)	Establishes Commission on Water Resource Management and Water Resource Management Fund
Executive Order 13751	2016	Federal	To prevent the introduction of invasive species and provide for their control, and to minimize the economic, plant, animal, ecological, and human health impacts that invasive species cause (amends EO 13112)
HB 2593 (amendment to HRS 91)	2018	Hawaii	Promotes the humane treatment of feral cats (HRS 91 allows agencies to adopt emergency rules in instances of imminent peril to public health, including livestock and poultry health)
7 CFR 360.200	2018	Federal	Designates certain plants as noxious weeds

- Executive Order 11990—Protection of Wetlands—authorized in 1977; requires federal agencies, in planning their actions, to consider alternatives to wetland sites and limit potential damage if an activity affecting a wetland cannot be avoided.
- 1987 State Water Code—The State of Hawai'i manages the use of surface and groundwater resources through the Commission on Water Resource Management (Water Commission), as mandated by the 1987 State Water Code (State of Hawai'i, 1987; DLNR, 1988a,b). However, in the State Water Code, there are no formal requirements that project proponents or the Water Commission protect the habitats of fish and wildlife prior to issuance of a permit to modify surface or groundwater resources. The State of Hawai'i considers all natural flowing surface water (streams, springs, and seeps) as State property (State of Hawai'i, 1987), and the Department of Land and Natural Resources (DLNR) has management responsibility for the aquatic organisms in these waters (State of Hawai'i, 1992).
- The Endangered Species Act of 1973 (ESA)—Protects critically imperiled species and their habitats from extinction. Wetlands and water bodies in Hawai'i provide habitat for many endangered plant, insect, and water bird species, and as a result receive protection through the ESA, and in particular, the protection of critical habitat for these listed species. Restoration efforts are often centered around these high quality habitats and therefore are not declining as rapidly as surrounding areas that lack these species and associated protections.

Despite the efforts of more than 20 State, Federal, and private agencies, unwanted invasive species are entering the State of Hawai'i at an alarming rate—about 2 million times more rapidly than the natural rate (CGAPS, 2009). In 1993, the Federal Office of Technology Assessment declared the State of Hawai'i's invasive species problem the worst in the nation. The State of Hawai'i's evolutionary isolation from the continents and its modern role as the commercial hub of the Pacific render the islands particularly vulnerable to habitat destruction by invasive species.

Summary of Interactions and Conservation Efforts

The primary stressors to wetlands include habitat loss and destruction caused by development, coastal flooding and inundation, introduction of invasive plants and animals, and contamination (Table 14). These stressors are significant and ongoing, act in concert with other stressors, and are expected to continue or increase in magnitude and intensity into the future without effective management actions to control or eradicate them. Current conservation efforts taken by Federal, State, private, and multiple agency partnerships combined with certain laws and regulations limit some of the effects of the stressors on wetland and open water bodies, but do not eliminate them. The stressors continue to contribute to the further increase of development, loss of species diversity, and loss of water resources. Without heightened levels of intensive and active management, wetlands and open water bodies will continue to be degraded and destroyed.

Of all of the wetland and open water bodies, those in low-elevation locations are most susceptible to major decreases in resiliency and representation due to human and climate-induced stressors. Though it is plausible that some of these habitats could see an increase in redundancy due to climatic stressors (expansion due to flooding and SLR), the plant and animal species found here have experienced reductions in numbers of populations and individuals which in turn reduces their representation. This leads to less resiliency to threats and stochastic events, and makes them vulnerable to future extirpation. The current level of ongoing conservation efforts at lowland wetland and open water body subtypes are not enough to keep them from continuous degradation. The low-lying subtypes near the coastline are also most vulnerable to expansive geomorphological changes caused by increased flooding events and SLR. Anchialine pools adjacent to the coastline could be completely lost. Although huge conservation gains have been made at Laysan Lake, this habitat is incredibly vulnerable to the effects of SLR and increased frequency of storms and flooding (USGS, 2013). There is little mitigation that can be implemented at this point to stop these inevitable impacts.

Table 14 Levels of resiliency, redundancy, and representation for wetland and open water bodies when exposed to current stressors compared to viability in their historic state.

<i>Sub-type</i>	<i>Stressor</i>	<i>Resiliency</i>	<i>Redundancy</i>	<i>Representation</i>
<i>Wetland</i>				
Upland bogs, marshes, and swamps	Human presence/abundance	Slight decrease	No change	Slight decrease
	Climate	Slight decrease	No change	Slight decrease
Lowland freshwater and saline marshes, and estuaries	Human Presence/Abundance	major decrease	decrease	major decrease
	Climate	major decrease	potential increase	major decrease
<i>Open water bodies</i>				
Fresh and saline lakes	Human presence/abundance	Decrease	No change	Decrease
	Climate	Decrease	Little change	Decrease
Anchialine pools	Human presence/abundance	Major decrease	Major decrease	Major decrease
	Climate	Major decrease	Major decrease	Major decrease
Ponds and artificial reservoirs ^a	Human presence/abundance	n/a	Major increase	n/a
	Climate	n/a	n/a	n/a

^aArtificial reservoirs were not historically considered a water body. However, there has been a major increase across the islands since pre-human contact.

Increased levels of restoration and conservation efforts such as fencing, ungulate control, invasive species management, and out-planting at high-elevation wetland subtypes has the potential to maintain the current native status or even reverse any ongoing degradation occurring for these habitats. Ponds and artificial reservoirs are the least susceptible to any of the discussed stressors and are therefore most likely to maintain their current level of viability.

Future Scenarios

The condition of wetlands and open water bodies in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

- (1) Conservation values: stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) Laws and biosecurity: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented. (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) Development or conservation planning: national, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011a,b; Miller, 2018).

Four foreseeable future scenarios were considered in this wetland and open water body assessment (Table 15). The future condition of wetlands and water bodies in scenario one, the status quo, was characterized from an assessment of change over time in land cover obtained from existing land cover maps. Based on these land cover maps, Reeves and Amidon (2018b) estimated an annual rate of change for wetland and water bodies, and projected little or no change (in area) through the year 2035. A slight increase is shown for Hawai'i and Ni'ihau while a slight decrease is expected for Maui. The sources of the increase are uncertain and may be related to ponds created for grazing. The loss on Maui and increase on Ni'ihau both are associated with reclassification to or from the Coast. These are likely mapping errors and not actual changes. Therefore, wetlands and open water bodies are expected to show little or no change in the foreseeable future. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of wetlands and water bodies that is expected in the foreseeable future under scenario one, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged.

Due to wetland mapping challenges discussed in previous sections, the future conditions of wetlands and water bodies for scenarios two, three, and four cannot be quantitatively (area) estimated. However, the scenario one estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of wetlands and open water bodies under scenarios two, three, and four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Reeves and Amidon, 2018a,b). Impacts from other sources of human activities or human-caused stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by non-native vegetation. For an assessment of island-by-island changes in human population, see Reeves and Amidon, (2018a,b).

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years

Table 15 Four foreseeable future scenarios considered in this wetland and open water body assessment.

<i>Future scenario</i>	<i>Description</i>
Future scenario one	Status quo—The most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future
Future scenario two	A slight increase in natural resource conservation in the CMPs marginally improves conservation management
Future scenario three	A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management
Future scenario four	A moderate to large increase in conservation actions in the CMPs substantially improves conservation management

(Solomon et al., 2009; Gillett et al., 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future viability.

Wetland and Open Waterbodies Future Scenario One—Status Quo

Scenario one is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in wetlands (Table 16).

Under scenario one, bogs and upland marshes and swamps would remain unchanged in size and distribution, therefore not affecting redundancy. Human-caused stressors will remain the same as there is minimal human interaction in these ecotypes. Ecological function is predicted to be reduced due to the ability of invasive plants and animals to outcompete native plants for water and space, subsequently resulting in a reduction in native biodiversity. Degradation of these native ecotypes will continue to increase, thus slightly reducing their resiliency and representation.

Lowland freshwater and saline marshes, estuaries, and anchialine pools are predicted to decline in size, distribution, ecological function, and quality due to the assumed expansion of the human population and continued development pressures resulting in a major decrease in resiliency, redundancy, and representation.

Fresh and saline lakes would remain unchanged in size and distribution, thereby not affecting redundancy. Lakes at upper elevations would experience the same stressors at corresponding levels as bogs and upland marshes and swamps, resulting in similar resiliency and representation levels.

Artificial reservoirs are expected to increase in distribution due to the assumed expansion of human population and continued development pressures for sewage treatment plants, golf courses resulting in a slight increase in resiliency, redundancy, and representation.

Table 16 Responses of wetland stressors in foreseeable future scenarios.

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable future scenarios and the resulting wetland conditions				
Use foreseeable future scenario one as a “baseline” to characterize changes in Conservation Actions and Conditions in future scenarios two, three and four	Scenario one: CMPs: Unchanged in support for NRC/B	Scenario two: CMPs: Small increase in support for NRC/B	Scenario three: CMPs: Small to moderate decrease in support for NRC/B	Scenario Four: CMPs: Moderate to large increase in support for NRC/B
	Conservation Actions: No change; current rate of land cover change continues through the foreseeable future. Condition: Area, quality, and sustainability slowly decrease through the foreseeable future.	Conservation Actions: Marginal increase Condition: Area is unchanged through the foreseeable future; quality and sustainability are slightly enhanced through the foreseeable future	Conservation actions: Substantial decrease Condition: Urban and agricultural uses are prioritized over conservation; area, quality, and sustainability substantially decrease through the foreseeable future	Conservation Actions: Substantial increase Condition: Robust, sustained effort to restore, manage, and expand conservation; area, quality, and sustainability substantially increase through the foreseeable future
Stressors	Responses of wetland and water body stressors			
Human presence/abundance				
Development	Small to moderate increase	No change (redevelop)	Moderate to large increase	Small to moderate decrease
Altered hydrology	No change to small increase	No change	Larger increase	Small decrease
Recreation/access	Small increase	Small increase	Larger increase	Larger increase
Water pollution	Small increase	No change	Larger increase	Small decrease
Invasive species	Small increase	Small increase	Larger increase	Small decrease
Climate				
Sea level	Small increase	Small increase	Small increase	Small increase
Storms	Small increase	Small increase	Small increase	Small increase
Drought	Small increase	Small increase	Small increase	Small increase
Air temperature	Small to moderate increase	Small to moderate increase	Small to moderate increase	Small to moderate increase

Future Scenario Two—There Is a Slight Increase in the CMPs That Marginally Improves Conservation Management

Scenario two has Conservation Agencies and stakeholders working with an increased but limited resources to slow or stop the degradation of landscape areas.

Under scenario two, bogs and upland marshes and swamps would remain unchanged in size and distribution, therefore not affecting redundancy. Human-caused stressors are predicted to remain unchanged or increase slightly as there is minimal human interaction in these ecotypes. Ecological function is predicted to be remain unchanged to slightly increase due to less competition with invasive plants and animals, thus slightly increasing their resiliency and representation.

Lowland freshwater and saline marshes, estuaries, and anchialine pools are predicted to decline in size, distribution, ecological function, and quality as the same level as in scenario one. The limited increase in resources to slow the degradation of these ecotypes will not significantly decrease the human and climate-caused stressors resulting in a slight decrease in a slight decrease in resiliency, redundancy, and representation.

Fresh and saline lakes would remain unchanged in size and distribution, thereby not affecting redundancy. Lakes at upper elevations would experience the same stressors at corresponding levels as bogs and upland marshes and swamps, resulting in similar resiliency and representation levels.

Artificial reservoirs would remain unchanged from scenario one because these are directly link with the assumed expansion of human population and development. Thus, this ecotype will retain its form and function, along with resiliency, redundancy, and representation into the foreseeable future.

Future Scenario Three—There Is a Small to Moderate Decrease in Conservation Actions in the CMPs That Substantially Decrease Conservation Management

All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible.

Under scenario three, bogs and upland marshes and swamps, lowland freshwater and saline marshes, estuaries, anchialine pools, and ponds would significantly decline in size, distribution, ecological function and quality due to their reliance on CMPs and conservation resources to address stressors to these wetland ecotypes. Degradation of these ecotypes and human-caused stressors in lowland wetlands will continue to increase as remaining areas become smaller, more fragmented and climate-caused stressors start appearing, thus reducing their resiliency, redundancy, and representation.

Fresh and saline lakes are not expected to decline in size or distribution in the foreseeable future, therefore not affecting redundancy. Human-caused stressors will increase overall and continue to reduce the ecological function and quality of fresh and saline lakes resulting in decreased resiliency, and representation.

Artificial reservoirs are predicted to increase in size and distribution due the to assumed expansion of the human population and continued development pressures from commercial, residential, and recreation, resulting in an increased resiliency, redundancy, and representation.

Future Scenario Four—There Is a Moderate to Large Increase in Conservation Actions in the CMPs That Substantially Improves Conservation Management

Scenario four is an overt and robust, active, ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of native wetlands, and to actively restore and expand them.

Under scenario four, bogs and upland marshes and swamps, lowland freshwater and saline marshes, estuaries, anchialine pools, and ponds would significantly increase in size, distribution, function, and quality from conditions in scenario one due to an overall decrease in wetland degradation and human-caused stressors. These wetland ecotypes are likely to expand as wetlands are protected from development, vegetation and water quality is increased, improved, and or restored, resulting in a significantly increase in resilience, redundancy, and representation.

Fresh and saline lakes are expected to remain unchanged in size and distribution from scenario one. These wetland ecotypes are expected to increase in function and quality due decrease in human-caused stressors resulting in an increase in resiliency and representation.

Summary

Based on our analysis of wetland and water bodies in Hawai'i, all wetlands and water bodies will decline in lieu of intensive management (Table 17). Scenarios one, two, and three are all plausible given the current and potential trajectories of stressors combined with alternate conservation outcomes. It seems unlikely that the substantially improved conditions detailed under scenario four would manifest given the intense effort it would take to reverse or mitigate such forces such as human development (population growth) and climate change.

Table 17 Summary of the expected viability (resiliency, redundancy, and representation combined) for each future scenario for wetland and open water bodies in the Hawaiian archipelago.

<i>Sub-type</i>	<i>Scenario 1: status quo</i>	<i>Scenario 2: slightly improved</i>	<i>Scenario 3: substantially decreased</i>	<i>Scenario 4: substantially improved</i>
Upland bogs, marshes and swamps ^a	No change to slight decline	No change to slight increase	Decrease significantly	Increase significantly
Lowland freshwater and saline marshes, estuaries, and anchialine pools ^a	No change to slight decline	No change to slight decrease	Decrease significantly	Increase significantly
Ponds and fresh and saline lakes ^a	No change or slight decline	Slight increase	Decrease significantly	Increase
Artificial reservoirs	No change	No change to slight increase	No change	Increase

^aFor these wetlands, "no change" is relevant for those areas currently fenced and managed. "Slight decline or increase" relates to those that are currently unmanaged.

Abstract

The Laurentian Great Lakes of North America are a series of interconnected lakes that, collectively, comprise one of the largest freshwater ecosystems on the earth. Prior to large-scale European settlement, the largely forested watersheds of the Great Lakes Basin delivered few nutrients to the lakes and the lakes themselves maintained a trophic status that ranged from oligo- to mesotrophic conditions. The biotic community of the Great Lakes is relatively depauperate, which reflects the recent geological development of the ecosystem. Historically, there were two main biotic communities in the Great Lakes: those that occupied the biologically less-productive open waters of the upper Great Lakes, and another in nearshore areas and productive embayments. Human activity in the Great Lakes Basin has brought with it a number of stressors, including land use changes, overfishing, altered nutrient loading and invasive species. To help manage these stressors, the management communities of the Great Lakes, which represent two countries, eight states, two provinces, tribal governments, First Nations, and local public agencies have developed a complex patchwork of governance in the Basin.

The Formation and Physical Environment of the Great Lakes

The Laurentian Great Lakes of North America are a series of interconnected lakes that straddle the international border between the United States and Canada (**Fig. 1**). Collectively, these five lakes are the largest freshwater ecosystem on the earth by surface area

Fig. 1 Satellite view of the Laurentian Great Lakes of North America.

Fig. 2 Map showing the depths of the Great Lakes and major landmarks.

(Lake Baikal is larger by volume) and contain approximately 21% of the surface freshwater on the entire planet. The Great Lakes were formed when the Laurentide Ice Sheet that covered much of North America during the last ice age gradually began melting during the Wisconsin glaciation between 12,000 and 10,000 years ago. Over the course of several thousand years, the ice sheet melted along its southern edge and filled the scoured lake beds, forming a series of proglacial lakes. Around 4000 years ago, the remaining ice dam receded beyond the northern edge of the Basin, establishing a connection between the newly formed Great Lakes and the St. Lawrence Seaway. In its present state, the Great Lakes Basin—an area that includes both the lakes and the watersheds that drain into them—covers an area approximately 240,000 km². In the direction of flow, the Great Lakes are comprised of Lake Superior, Lakes Michigan and Huron, which are separate basins of a single lake that is connected by the Straights of Mackinaw, Lake Erie and Lake Ontario. Retention times vary according to the surface area, depth and predominant current patterns of each lake, with the longest retention time of 191 years in Lake Superior, and Lake Erie having the shortest retention time of 2.6 years. Water flowing through the Great Lakes ultimately drains to the Atlantic Ocean via the St. Lawrence Seaway (Fig. 2).

Prior to European settlement in the Basin, the Great Lakes maintained a trophic status that ranged from oligo- to mesotrophic. The surrounding watersheds of the Basin were largely comprised of forested land prior to settlement and, therefore, delivered few nutrients to the lakes. Coastal wetlands often occupied the space between the land in the watershed and the nearshore waters of the lakes in lower gradient watersheds around the Great Lakes Basin. These wetlands likely further reduced nutrient delivery from the watershed. Within the lakes themselves, cycles of thermal stratification and primary production were tightly linked in an annual cycle. The deeper, open waters of the Lakes Superior, Michigan, Huron, Ontario and the Central and Eastern Basins of Lake Erie can be characterized as dimictic and are prone to stratification during the winter and summer, with periods of turnover and isothermal periods that occur with warming during the spring and cooling during the fall. During isothermal periods, lake temperatures remain near 3–4 °C and intense winds during the fall and early spring promote complete mixing of the water column even in some of the deepest points of the lakes. Shallower areas, such as the Western Basin of Lake Erie and coastal embayments such as Green Bay in Lake Michigan, Saginaw Bay in Lake Huron and Bay of Quinte in Lake Ontario, are among the first areas of the lakes to freeze during winter but lack sufficient depth to experience prolonged summer stratification.

Historical Biological Communities of the Great Lakes

Compared to ecosystems of similar size, the biotic community of the Great Lakes is relatively depauperate, which reflects the recent geological development of the system (Fig. 3). At the base of the food web, the annual cycle of primary productivity throughout the Great Lakes has historically been closely linked with seasonal thermal stratification with a peak of primary production occurring during a spring bloom of mostly centric and pennate diatoms and other green algae. The spring bloom is then followed by a summer clear water phase that often coincides with proliferation of herbivorous zooplankton. During the summer clear water phase, the highest level of primary production may occur deeper in the water column at a point called the deep chlorophyll maximum, which is often at the deepest point where light attenuation, nutrients and thermal stratification can sustain phytoplankton growth. Finally, a second, less-pronounced peak of primary production occurs during the fall. Relatively little is known about primary production in the Great Lakes during the winter, but limited studies have shown that diatom production under the ice can be a significant contributor to annual estimates of algal biomass in some lakes (Revie et al., 2016).

Fig. 3 A representation of the Great Lakes food web prior to European settlement in the basin.

The zooplankton communities in surface waters of the Great Lakes are comprised of three major groups: rotifers, copepods and cladocerans. Rotifers are an important contributor to total zooplankton biomass and their community composition tends to vary according to the trophic state of each particular lake. Some genera, such as *Filinia*, *Brachionus* and *Trichocera*, are more commonly found in highly productive areas like western Lake Erie whereas other genera, such as *Conochilus* and *Kellicottia*, are more common in the oligotrophic waters of the upper Great Lakes (Barbiero and Warren, 2011). Historically, the crustacean zooplankton communities of the Great Lakes display a pattern of seasonal succession that is comparable to many other lentic ecosystems. Calanoid and cyclopoid copepods (common genera include *Limnocalanus*, *Leptodiatomus* and *Mesocyclops*) and their copepodites represent the dominant taxa present during the spring and early summer. As water temperatures and primary production increase through the summer, zooplankton community composition typically shifts towards an increasing relative abundance of cladocerans, including many herbivorous species (*Daphnia*, *Holopedium* and *Bosmina* are common genera) and the predatory cladoceran *Leptodora kindtii*. Beyond seasonal succession, many species of zooplankton in the Great Lakes also undergo pronounced diel vertical migration (DVM), especially during the summer months when stratified conditions are present in the lakes. Species that undergo DVM include many species of *Daphnia*, which spend daylight hours in the deeper waters of the metalimnion, presumably hiding from visual predators near the surface, and migrate upwards to feed near the surface during the night. Other zooplankton taxa, such as *Limnocalanus*, exhibit similar DVM behavior but migrate between the hypolimnion, which they inhabit during daylight hours, and then migrate upwards to the metalimnion during the night, presumably to feed on both algae and smaller zooplankton that are concentrated near the deep chlorophyll layer.

Benthic habitats are typically an understudied component in aquatic ecosystems, and the benthic habitats of the Great Lakes are no exception. However, zoobenthic species can be important contributors to whole-lake secondary production and often play important roles in ecosystem processes, and this is true for the Great Lakes as well. The historical zoobenthic community in the Great Lakes consisted of two main assemblages: one associated with shallow and productive waters, and another associated with deeper, less productive offshore waters. Community diversity was highest in shallow, productive habitats, where many depth-restricted taxa reside, including many species of Oligochaete worms in the family Naididae, as well as common aquatic insect larvae in the families Chironomidae and Ephemeroptera, Hirudinae, Gastropods, and native freshwater mussels in the family Unionidae. In deeper offshore habitats, the zoobenthic community of the Great Lakes was historically dominated by two species of crustaceans, *Diporeia* and *Mysis*, which are important diet items for many different fish species and also represent an important link between benthic production and the pelagic food webs of the upper Great Lakes.

The Great Lakes are home to about 140 native fish species, and the fisheries that the lakes support are an important part of the region's culture and economy. Historically, there were two main types of fish assemblages across the Great Lakes Basin: one typified by the fish community of the open waters of the upper Great Lakes, and another in nearshore areas and productive embayments. In the low productivity waters of Lakes Superior, Michigan, Huron, Ontario and the offshore waters of Eastern Lake Erie, the fish assemblage mainly consisted of salmonines, coregonids and sculpins. Lake Trout (*Salvelinus namaycush*) and Burbot (*Lota lota*)

were the top predators in the offshore food web, and other abundant species included Lake Whitefish (*Coregonus clupeaformis*), Slimy Sculpin (*Cottus cognatus*) and Deepwater Sculpin (*Myoxocephalus thompsonii*). Ciscoes, in both shallow water form (formerly lake herring, *Coregonus artedii*) and the deepwater chubs (*Coregonus* spp.), were an important component of the offshore food web as well (Eshenroder and Burnham-Curtis, 1999). In the shallow and productive areas of the Great Lakes, including the Western Basin of Lake Erie and embayments such as Green Bay in Lake Michigan, Saginaw Bay in Lake Huron, and Bay of Quinte in Lake Ontario, percids, cyprinids and centrarchids were abundant. In these areas, Blue Pike (*Sander vitreus glaucus*) and Walleye (*Sander vitreus*) were the top predators, and other abundant species included Yellow Perch (*Perca flavescens*) and Emerald Shiner (*Notropis atherinoides*) (Eshenroder and Burnham-Curtis, 1999). Lake Sturgeon (*Acipenser fulvescens*) were another important component of the historical nearshore fish assemblage that occupied many of the coastal embayments of the Great Lakes and their tributaries.

Ecosystem Stressors

Human activity in the Great Lakes Basin has brought with it a number of stressors, beginning with the European settlement of the region and the subsequent changing of land-use patterns within the watershed. By the early 18th century, some of the first dams were built in the Great Lakes Basin (Beeton et al., 1999), which blocked access to important spawning habitats for migratory fish species such as Lake Sturgeon and Walleye. The presence of the dams also changed the natural flow regimes of the tributaries and, subsequently, altered nutrient dynamics in the lakes themselves (Hayes, 1999). As more people came to reside in the Great Lakes Basin throughout the early 20th century, human activities in the watersheds related to natural resource extraction, such as timber harvesting and mining, further altered land use patterns in the watersheds. The growing human populations also had a direct effect on land use patterns, as people began converting forests and wetlands into agricultural fields and urbanized areas. Coastal wetlands, which provide important breeding or nursery habitats for many Great Lakes fish species, were dramatically altered throughout this settlement period. For example, over 90% of the coastal wetlands surrounding western Lake Erie and the Detroit River have been removed due to human activity such as draining and diking (Maynard and Wilcox, 1997).

The growing human population in the Great Lakes Basin continued to stress the lake ecosystems beyond the changes occurring in the watershed. By 1829, with the completion of the Erie and Welland canals, the once-isolated Great Lakes became hydraulically connected to the Atlantic Ocean and commercially connected with population centers along the east coast. In particular, the construction of the Welland Canal allowed nonnative species to bypass Niagara Falls, which had served as natural barrier between Lake Erie and Lake Ontario since the initial formation of the lakes, to access the four upper Great Lakes. Two fish species in particular, the parasitic Sea Lamprey (*Petromyzon marinus*) and the planktivorous Alewife (*Alosa pseudoharengus*), entered the upper Great Lakes through the Welland Canal with devastating consequences for the native fish populations. Around this same time period, commercial fisheries were becoming well-established in the Great Lakes, and increasing fishing efforts as well as improvements in fishing technology had already reduced native fish abundance across all five Great Lakes. However, the combined effects of invasive species proliferation and direct fishing mortality had cascading effects on the native fish populations of the Great Lakes. By the 1950s, the combined effects of parasitism by Sea Lamprey and intense fishing pressure led to the collapse of Lake Trout populations in Lakes Michigan, Huron, and Ontario. A similar dynamic was responsible for the extinction of three of the larger morphs of the deepwater chubs in the upper Great Lakes (*Coregonus nigripinnis*, *C. johannae*, and *C. reighardi*). As the combined effects of sea lamprey predation and fishing mortality eliminated the larger morphs of the deepwater chubs, both lamprey and commercial fisheries shifted to focus on smaller species, ultimately reducing the abundance of Lake Whitefish (*Coregonus clupeaformis*) and Ciscoe (*Coregonus artedii*). With the near-elimination of predatory lake trout and native planktivorous fish, alewives became incredibly abundant in the open waters of the Great Lakes and further stressed native fish populations through predation on the planktonic larvae of lake trout, yellow perch, and walleye (Madenjian et al., 2008). By the 1960s, Pacific salmon were being stocked into the Great Lakes in large numbers to help control the booming alewife populations and to provide anglers with sportfishing opportunities (Fig. 4).

Through time, the watersheds of the Great Lakes Basin became increasingly industrialized, which further stressed the ecosystem. Polychlorinated biphenyls (PCBs) are a class of synthetic organic chemicals that were globally manufactured and widely used as insulators with long-term degradation resistance. PCBs can be found in sediments, waters, biological tissues, wastes, air, and certain in-use products due to their high stability (United States and Canada, 2018). Their presence can cause a variety of harmful environmental and human health effects. While Canada and the United States have restricted the manufacturing and importation of PCBs since the 1970s, PCBs still today contribute to fish consumption restrictions in the Great Lakes Basin. By the 1960s, the cultural eutrophication of the Great Lakes due to excessive nutrient loading from both point and non-point sources had become a major concern (Beeton, 1965). Although open waters remained mostly oligotrophic, nearshore areas such as the Western Basin of Lake Erie, and coastal embayments such as Saginaw Bay and Green Bay, commonly experienced negative consequences from excessive nutrient loadings such as harmful algal blooms and severe bottom hypoxia during the summer (Vollenweider et al., 1974). The ships that conduct transoceanic commerce across the waters of the Great Lakes have brought more than just goods to the region; the ballast water that stabilizes these ships also serves as a vector for invasive species from around the globe. Entering through the ballast water of foreign ships, a series of invasions by nonnative species, dreissenid mussels from the Ponto-Caspian region (zebra and quagga mussels, *Dreissena polymorpha* and *D. bugensis*), in particular, have caused major changes in Great Lakes ecosystems (Fig. 5). When dreissenids reach large population sizes, they sequester primary production in nearshore benthic habitats, which acts to constrain nutrients that would otherwise be available to higher trophic levels in offshore areas (Hecky et al., 2004).

Fig. 4 A representation of the Great Lakes food web in the mid 20th century.

Fig. 5 A representation of the current Great Lakes food web.

Since the 1980s, the physical environment of the Great Lakes has been altered in ways that are consistent with global climate change. Recent documented changes include increases in surface water temperatures (Dobiesz and Lester, 2009), reduced iced cover during the winter, a prolonged stratification period during the summer (Wang et al., 2012), and large fluctuations in water levels (Clites et al., 2014). However, the management communities of the Great Lakes have, thus far, viewed climate change as an interactor with existing ecosystem stressors rather than address the direct effects of climate change (Collingsworth et al., 2017). Surface temperatures in the waters of the upper Great Lakes will increase due to climate change, which may make these areas more

susceptible to the dispersal and colonization of invasive species (Mandrak, 1989). In addition, climate change models consistently forecast increasing precipitation and more pronounced storms during the spring across the upper Midwestern United States. Such changes in seasonal hydrology will influence the presence and severity of harmful algal blooms and seasonal hypoxia in productive areas of the basin such as the Western and Central basins of Lake Erie (Watson et al., 2016). Climate adaptation for the ecosystems of the Great Lakes will rely on the ability of managers to understand and mitigate the interacting effect of these common stressors because they are widespread across the Basin. A recent multi-stressor mapping effort found that many areas important for fisheries, in particular nearshore areas and coastal embayments of Lakes Michigan and Huron, and much of Lakes Erie and Ontario, experienced high cumulative stress (Allan et al., 2013).

Binational Governance of the Great Lakes

The Great Lakes are shared and governed by two countries, eight states, two provinces, and numerous Indian tribes and First Nations, in addition to a multitude of American, Canadian, and international agencies, as well as thousands of local governments (Hall, 2006; Bielecki, 2007). A complex patchwork of governance exists in the Basin, owing to overlapping environmental and natural resources within the Great Lakes system, and similarly overlapping populations concerned with specific resources and functions, as detailed in a review of Great Lakes governance and law by Hall and Houston (2014).

The Great Lakes Basin's two binational treaty organizations are the International Joint Commission (IJC) and the Great Lakes Fishery Commission (GLFC). The IJC was established under the 1909 Boundary Waters Treaty (BWT) and works to prevent and resolve boundary waters disputes between Canada and the United States. The BWT has provided the principles for Canada and the United States to follow in using their shared, or transboundary, waters for over a century (Hall, 2007). The IJC serves as an independent and objective advisor to the two governments related to implementation of the *Great Lakes Water Quality Agreement* (GLWQA). The six politically-appointed IJC Commissioners are advised by more than 20 binational boards and task forces, including the Great Lakes Water Quality Board and the Great Lakes Science Advisory Board, which advise the IJC on policy and scientific matters related to Great Lakes water quality. The IJC also provides oversight of efforts to regulate water levels and flows in some of the Great Lakes and connecting channels. The Great Lakes Fishery Commission (GLFC) facilitates cross-border cooperation of state, provincial, tribal, and federal fishery management agencies for the improvement and preservation of the fisheries under *A Joint Strategic Plan for Great Lakes Fisheries Management* (GLFC, 2007). The Lake Committees of the GLFC are binational committees (except for the Lake Michigan Committee, which does not have Canadian representation) comprised of senior officials from state, provincial, and tribal fishery management agencies. The Lake Committees are tasked with sustainably and cooperatively managing Great Lakes fisheries resources and the fish community, considering issues and problems of common concern to the jurisdictions, developing and coordinating joint state/provincial/federal fisheries programs and research, and making recommendations regarding fisheries management issues affecting the Great Lakes. The Lake Committees also develop and maintain shared fish community objectives, establish appropriate stocking levels and harvest targets, set law enforcement priorities, and formulate management plans. Together, the IJC and the GLFC have facilitated the development of ecosystem-based fisheries management in the Great Lakes, which integrates abiotic, biotic, and social components into decision-making with the goal of improving both natural resources health and ecosystem sustainability (Guthrie et al., 2019).

The original GLWQA, as established in 1972 under the BWT, was signed by U.S. President R. M. Nixon and Canadian Prime Minister P. Trudeau on April 15, 1972, and is recognized as the first multi-national agreement designed to protect and resuscitate a shared environmental resource (Holden, 1972). The 1972 GLWQA set specific water quality objectives for a limited number of parameters, included interim objectives for a wider variety of substances, and called for the control of pollution from industrial sources, shipping and dredging activities, and onshore and offshore facilities, and a reduction in phosphorus loading to the Great Lakes (Barbiero et al., 2018). A significant change in the 1978 amendment to the GLWQA was its stated goal "to re-store and maintain the chemical, physical, and biological integrity of the waters of the Great Lakes Basin Ecosystem"; this shift in emphasis to an "ecosystem approach" adopted a far broader goal than that of its 1972 predecessor, which had focused on the improvement of water quality through pollution control (GLWQB, 1986; Barbiero et al., 2018). The 1978 GLWQA defined the Great Lakes Basin Ecosystem as "the interacting components of air, land, water, and living organisms, including man, within the drainage basin of the St. Lawrence River at or upstream from the point at which this River becomes the International Boundary between the United States and Canada" (GLWQA, 1978), thus recognizing the connection and influence of humans to the structure, function, and processes of the Great Lakes Basin (Guthrie et al., 2019). The GLWQA was further amended in 1983, 1987, and, most recently, in 2012. The 2012 protocol amending the GLWQA reaffirms the United States' and Canada's determination "to protect, restore, and enhance water quality of the Waters of the Great Lakes and their intention to prevent further pollution and degradation of the Great Lakes Basin Ecosystem" (Canada and the United States, 2012).

Another pivotal guiding document in the implementation of ecosystem-based management in Great Lakes was the 1981 *A Joint Strategic Plan for Management of Great Lakes Fisheries* (GLFC, 1981; Guthrie et al., 2019). Signed by the Great Lakes states, the Province of Ontario, and federal agencies, and later amended to include intertribal organizations in the Great Lakes Basin (Gaden, 2007), *A Joint Strategic Plan* transformed the GLFC Lake Committees from information-sharing forums into strategic decision-making entities (Guthrie et al., 2019). This transformation was accomplished by the establishment of jointly-developed fish community objectives for each lake that (1) clarified the fishery management goals, and (2) established environmental objectives needed to support

the fish community objectives (GLFC, 1997; Guthrie et al., 2019). Implementers of the 2012 GLWQA and A *Joint Strategic Plan* are working closely together to implement ecosystem-based management in the Great Lakes.

In addition to federal treaty power, federal environmental lawmaking and natural resources management has been integral in protecting and restoring the Great Lakes ecosystem. The passage of the Clean Water Act in 1972 is recognized as the most significant exercise of federal regulation relevant to the Great Lakes (Hall and Houston, 2014). The Clean Water Act strives to create a partnership between the states and the federal government “to restore and maintain the chemical, physical, and biological integrity of the Nation’s waters” (Federal Water Pollution Control Act Amendments of 1972). To achieve this goal, the Clean Water Act creates several regulatory and funding programs (detailed in Hall and Houston, 2014), including effluent limitations promulgated by the U.S. Environmental Protection Agency. The Coastal Zone Management Act (CZMA) of 1972 provides the basis for protecting, restoring, and responsibly developing U.S. coastal communities and resources. The National Coastal Zone Management Program is a voluntary partnership between the federal government and U.S. coastal and Great Lakes states and territories authorized by the CZMA and administered by NOAA. A wide range of issues are addressed through the program, including coastal development, water quality, public access, habitat protection, energy facility siting, ocean governance and planning, coastal hazards, and climate change.

Local sovereignty of the eight states and the providence of Ontario and interstate governance are also important components of Great Lakes law and policy (Hall and Houston, 2014). Tribal governance and the sovereignty of tribal nations also play a key role in the management of the Great Lakes (Hall and Houston, 2014). Tribes and tribal Great Lakes governance bodies manage tribal water and fishery resources. More recently, the Great Lakes Basin Compact, first signed in 1955, includes each of the eight Great Lakes states as members and creates a Great Lakes Commission comprised of representatives from the member states, with the Canadian provinces of Ontario and Quebec designated as associate members. The Great Lakes governors and premiers negotiated the 2008 Great Lakes–St. Lawrence River Basin Water Resources Compact and the Great Lakes–St. Lawrence River Basin Sustainable Water Resources Agreement to manage new or increased water withdrawals in the Great Lakes Basin. The Agreement is a nonbinding policy between the states and provinces that creates a governance structure to set standards for water use and withdrawals administered primarily under the authority of individual states and provinces (Hall and Houston, 2014).

Management Opportunities

In response to the persistent stressors that negatively impact the Great Lakes, recent management initiatives have been implemented to restore these ecosystems back to their original state. To reverse the cultural re-eutrophication of Lake Erie, along with the growing threat of harmful algal blooms and the expansion of summer hypoxia, the United States and Canada adopted phosphorus reduction targets in 2016. The new targets call for an overall 40% reduction in total phosphorus loads from the Maumee River, and other sources in the western and central portions of the Lake Erie basin. In keeping with the bi-national management strategies of the Great Lakes, each country has developed detailed action plans which outline strategies for meeting the new target phosphorus loads.

In the upper Great Lakes, the proliferation of Dreissenid mussels into deep water habitats has altered the food webs in such ways that they resemble the ecosystems as they existed prior to the industrialization of their watersheds. Productivity is low across all trophic levels, alewife populations have been dramatically reduced and Lake Trout, the top native predator in the ecosystem, has been making a comeback. In this environment, fisheries managers have chosen to promote the reintroduction and stocking of native planktivores, such as ciscoes, in an attempt to promote native species.

Abstract

The African Great Lakes (AGL) are among the most ecologically and economically important aquatic biomes of the world. They are sources of nutritious fish in a region where malnutrition and poverty levels are high, provide employment to fisher communities, and are sources of water for domestic and urban use, hydropower generation, irrigation and wastewater disposal. Some of the lakes have the highest diversity of endemic freshwater fishes and other organisms on earth. The original biogeography of AGL was molded by geological events. Here we examine how the biogeography of AGL has been altered by activities of a rapidly increasing human population whose growth rate is among the fastest in the world through land use change, fishery exploitation, and climate variability and change. Fisheries exploitation was the first to manifest resulting into a decline and in some cases total disappearance especially of some large inshore fish species which, in some lakes led to enhancement of fish production through introduction of new fish species and cage aquaculture. The impacts of conversion of land to agriculture, deforestation, wetland degradation, urban and hydropower developments were cumulative since the turn of the 20th century and their effects on aquatic ecosystems manifested at different rates through changes in physical and chemical conditions, shifts in algal and invertebrate communities and fish stocks, and proliferation of invasive weeds. Some of the lakes with terrestrial game reserves around them were partly shielded from these changes. Climate variability and change, which intensified after the 1970s, triggered further environmental changes, algal communities shifted from large diatoms to smaller diatoms, green algae, and blue green algae, invertebrates from larger to smaller sized groups, and fish stocks became dominated by small pelagic species. These changes have been more severe in shallower lakes or shallow near-shore areas of deep lakes with high human population growth rates and densities. The changes are expected to continue and should be monitored and managed to avoid reaching catastrophic levels. The countries sharing the lakes should network within and between lakes, nationally, regionally, continentally and globally to mobilize and harmonize information and data, and update it regularly to guide management of lakes.

Background

The African Great Lakes, AGL (Malawi, Tanganyika, Kivu, Edward, Albert, Victoria, and Turkana), are in the African Rift Valley region between 14° 40'S–4° 31'N and 28° 50'E–36° 42'E (Fig. 1). The only similar regions of Great Lakes in the world are the Laurentian Great Lakes of North America with five lakes; Superior, Michigan, Huron, Erie and Ontario (Bootsma and Hecky, 2003), but these lie in a single watershed, are shared between the United States of America and Canada, and have a much lower number of fish species (179). The AGL were formed by tectonic activity and hold one-third of the world's surface freshwater. Unlike the Laurentian Great Lakes which are directly joined to each other and lie at almost the same elevation, the AGL are distinct and vary considerably

Fig. 1 African Great Lakes and the human population density in their basins. There are over 15 small lakes with internal drainage in the Eastern arm of the rift valley which have been numbered in addition to those labeled. The basin population is from the world population information. The other Great Lakes of the world are the Laurentian Great lakes of North America (A), the Caspian Sea (B), and Lake Baikal (C).

Adapted initially from ILEC (International Lake Environment Committee) (2005). Managing Lakes and Their Basins for Sustainable Use: A Report for Lake Basin Managers and Stakeholders, 142pp. Kusatsu, Japan: International Lake Environment Foundation and Herdendorf CE (1982) Large lakes of the world. *Journal of Great Lakes Research* 8(3): 379–412 and improved from different literature sources in the MS.

in their geological characteristics (Table 1; Herdendorf, 1982; ILEC, 2005). They are located in separate sub-basins and the different sub-basins traverse the African continent draining into the Mediterranean in the north, the Indian Ocean in the east and the Atlantic Ocean in the west with one (Lake Turkana) lying in a closed basin. Although regarded as a single lake region, the AGL can be likened to islands and the fauna of even those that are connected is separated by water falls. Their morphometry, age and diverse habitats have enabled them to develop unique, endemic fish faunas and other organisms. An outstanding feature of the AGL compared to the Laurentian Great Lakes is their range of age and morphometry (Table 1), which has not only allowed for evolutionary change but has contributed to the high biodiversity and influenced the impacts of human activities on individual lakes.

The AGL are shared among 10 countries (Mozambique, Malawi, Zambia, Tanzania, Democratic Republic of Congo DRC, Rwanda, Burundi, Uganda, Kenya, and Ethiopia). They are remarkable for being the most species-rich freshwater ecosystems on earth with over 2000 fish species most of them endemic (Eschmeyer and Fong, 2018). They are important sources of highly nutritious fish with high levels of proteins, essential amino acids, vitamins and minerals such as calcium, iron and zinc, which are all important in fighting malnutrition and have health benefits. The fisheries of the lakes provide employment to thousands of people within their basins and many more along the value chain. They are reservoirs of water for domestic, industrial use, and agriculture. There are many urban areas along their shores and in their basins some of which discharge wastes into the lakes. The lake are important transport routes. Many of lakes have hydropower plants on the rivers that flow in or out of them which provide the energy much need for development. Some of the lakes have oil and mineral reserves and developments in the lakes and their basin. Many of the lakes have terrestrial national parks which are important for tourism and which, in some cases shield the lakes from land based degradation. They are also important in modulating local climate.

The way the original biogeography of the AGL was shaped by geological history has been extensively examined (e.g., Beadle, 1962, 1981; Fryer and Iles, 1972; Salzburger et al., 2014) and is, therefore not the focus of this review. The review focuses on how anthropogenic drivers due to economic demands of a rapidly increasing human population, especially in the lake basins, including habitat degradation; resources exploitation; fish species introductions; climate variability and change, and emerging stressors such as cage aquaculture (Musinguzi et al., 2019), have and are expected to continue altering the biogeography of the AGL. We also highlight the information and data needs to guide policies, and the institutional frameworks for management of the lakes. This article contributes to advancement and actualization of the process that was set by the African Great Lakes Conference of May 2017 (Doran et al., 2018) to stimulate action on networking and sharing information and data of the AGL and other lakes of the world. The review, focuses on four key questions:

- (i) What are the main drivers of biogeography of the AGL?
- (ii) What have been the trends in the drivers on the different AGL?
- (iii) How can the drivers be managed to sustain the biogeography of the AGL to enable the lakes provide the desired ecosystem and livelihood services?
- (iv) What institutional arrangements are required to manage the drivers?

The Main Drivers

Chronology of the Main Drivers

At the beginning of the 20th century the biogeography of the AGL and associated small lakes and rivers were in a virtually pristine state shaped by geological events. As the human population has increased, the biogeography has increasingly been altered by the demands of a rapidly increasing human population due to: over-fishing; land use change; and climate variability and change. These have contributed to changes in nutrients, pollutants, algae, invertebrates, fish stocks, and proliferation of invasive species (Table 2).

Table 2 The chronology of events that have contributed to alteration in biogeography of the AGL.

Period	Events and main source of information
Before 1900	Biodiversity and environment of AGL in a pristine state with fish stocks and environment little affected by anthropogenic factors (Hecky et al., 2010)
1900 onwards	Increases in human population intensifies and accelerates land use change due to conversion of land to agriculture, deforestation, wetland degradation, dam constructions, urbanization, and mineral development resulting in nutrient enrichment and pollution (Hecky et al., 2010; Otu et al., 2011)
1900–1950	Fishing effort intensifies with improvement in fishing gear, crafts and access to markets, leading to a decline and collapse of some of some especially larger lake fish species such tilapias and riverine species such as <i>Labeo</i> (Jackson, 1971; Ogutu-Ohwayo, 1990)
Mid 1950s	Non-native fishes (Nile perch, tilapias) are introduced into lakes Victoria, Kyoga and other lakes in their basin, and clupeid into Lake Kivu to improve fish production (Jackson, 1971; Ogutu-Ohwayo, 1990; Ogutu-Ohwayo and Hecky, 1991)
Late 1970s	Trawl fishery is introduced on lakes Victoria and Malawi followed by a decline in haplochromine stocks (Turner, 1977; Ogutu-Ohwayo, 1990)
1970 onwards	Stocks of introduced tilapias especially, Nile tilapia are established in lakes Victoria and Kyoga replacing the native tilapias (Ogutu-Ohwayo, 1990)
1970 onwards	Climate variability and change intensifies contributing to changes in lake levels, and aquatic productivity processes (Ogutu-Ohwayo et al., 2016)
1970–1990	Eutrophication and pollution manifests accompanied by changes in algae, invertebrate, and fish communities, water transparency, and anoxic conditions in Lake Victoria with similar symptoms in other lakes such as Malawi (Hecky et al., 2010; Otu et al., 2011)
Late 1980s	Water hyacinth, <i>Eichhornia crassipes</i> infests lakes Victoria, Albert, Kyoga, and other African lakes (Twongo, 1996)
1980–1990	Stocks of Nile perch in lakes Victoria and Kyoga increase rapidly followed by a contemporaneous rapid decline and disappearance of most haplochromine species and the lakes becomes dominated by the introduced Nile perch and Nile tilapia, and only one native species, <i>Rastrineobola argentea</i> (Ogutu-Ohwayo, 1990)
1990 onwards	Stocks of Nile perch in Victoria decline with increasing fishing effort followed by resurgence of some haplochromine species dominated by pelagic zooplanktivores and detritivores (Kishe-Machumu et al., 2015)
1990 onwards	Fish stocks in lakes Victoria, Albert, Malawi and Kyoga become dominated by pelagic species as in lakes Tanganyika and Kivu (Mangeni-Sande et al., 2019)
2000 onwards	Cage aquaculture is introduced on lakes Malawi, Tanganyika, Kivu, Victoria, Albert, and other African lakes to boost fisheries production (Musinguzi et al., 2019)
2010	The Kariba weed, <i>Salvinia molesta</i> infests Kyoga and Victoria (Wanda pers. com.)

Human Population

The economic demands of an increasing human population have been the main driver of alteration in biogeography of the AGL since the turn of the 20th century (Bootsma and Hecky, 1993). The basins of the AGL have a human population growth rate of 2–5% per year, which is among the highest in the world (PRB, 2014); and a high human population density of up to 500 persons km⁻² which varies between the lake basins (Fig. 1). The highest population density is around Lake Victoria and lowest around Lake Turkana where the population density is also very high in the Omo valley which supplies most of the water to the lake (Fig. 1). About 60–70% of the people in the AGL region depend on agriculture for their livelihood (OECD-FAO, 2016) and there are many economic activities in the lake basins.

Fishery Exploitation

Fishery exploitation was the first driver to manifest changes on the AGL through the decline, and in some cases complete disappearance, especially of the larger native fish species (Graham, 1929; Worthington, 1929; Jackson, 1971; Ogutu-Ohwayo, 1990). Prior to 1910, fisheries of the AGL were exploited for subsistence purposes in near-shore areas using traditional fishing gear such as basket traps, hooks and papyrus seines. The situation changed following introduction of flax and nylon gillnets, improvement in fishing crafts, introduction of outboard engines and improved access to markets. This increased fishing effort (Jackson, 1971; Ogutu-Ohwayo, 1990). The rates of depletion of native fish species have been different depending on habitat, susceptibility, and apparent resilience of individual fish species. The species that were restricted to shallow inshore areas of water bodies or migrated from the lakes to the rivers to breed declined and disappeared first as they were more easily accessible to fishermen.

The decline in native fisheries in some lakes led to introduction of non-native fish species to boost production. In Lake Victoria, this resulted in introduction of a large piscivorous predator, Nile perch (*Lates niloticus*) and four tilapiine species: *Oreochromis niloticus*, *O. leucostictus*, *Coptodon zilli*, and *C. rendalli* during the 1950s following the collapse of the fishery of the native *Oreochromis* species (Ogutu-Ohwayo, 1990). Introduction of the Lake Tanganyika clupeids (*Limnothrissa miodon* and *Stolothrissa tanganyikae*) into Lake Kivu was, however done to improve fish productivity in an impoverished fishery.

Fig. 2 Cages in Napoleon Gulf of Lake Victoria. Note the algal bloom near the cages. Photograph from personal field file.

Cage aquaculture (**Fig. 2**) started on Lake Malawi 2004 to enhance fish production and has expanded rapidly on some AGL and other lakes in Africa (Musinguzi et al., 2019). Most cages are located in shallow areas of aquatic systems and can impact critical biodiversity and breeding areas if not well managed. It can also increase nutrient enrichment and pollution from food wastes, fecal materials, and therapeutics (Gondwe et al., 2011) as well as introduction of invasive species.

Land Use Change

The economic activities of the rapidly increasing human population have been the main driver of alteration in biogeography of the AGL due to conversion of land and degradation of the forest cover as well as critical habitats such as wetlands. This has enhanced siltation and nutrient enrichment of the lakes and exposed the lakes to pollutants and contaminants from land, resulting in loss of critical habitats. The near-shore areas of most of the AGL are increasingly being urbanized, with areas like those around Lake Victoria with the highest human population density, expected to become completely urbanized by 2030 (Seto et al., 2012). Dams have been, and continue to be constructed along the major rivers flowing in and out of the lakes in the AGL region to provide the hydro-power needed for development which affects the environment and biodiversity of rivers and associated lakes (Kano et al., 2016). Oil and gas have been discovered in some of the lakes and their basins (e.g., methane in Kivu and oil in Albert) and exploration and exploitation can degrade the habitats if not properly done. Contaminants from the different human activities have accumulated into aquatic systems overtime further impacting their habitat. This has changed physical, chemical, and biological conditions of aquatic systems.

One of the manifestations of a changing environment was the invasion of the lakes in the AGL region by invasive weeds as the environment of the lakes became altered (**Fig. 3**). Water hyacinth (*Eichhornia crassipes*) infected lakes Victoria and Kyoga in 1980s (Twongo, 1996) and has been reported in the basins of other AGL including Malawi, Tanganyika, and Turkana, and has the potential to disrupt ecosystem services and economic activities. The other problematic plant is the Kariba weed (*Salvinia molesta*), which first occurred on Lake Kariba in the AGL region in the early 1960s following creation of the Kariba dam (Mitchell and Rose, 1979) but has increased in the Kyoga, Victoria and Albert Lake regions since the late 1990s. *Prosopis juliflora* is another weed that was introduced into Lake Turkana with the hope of greening the desert but became invasive and has since spread along inshore waters of the lake disrupting inshore breeding grounds and critical habitats for fish (Avery, 2013). These weeds have mainly altered shorelines, especially of shallow lakes and the nutrient rich shallow near shore areas and bays of deep lakes and rivers, which are areas of high biodiversity and critical breeding and nursery habitats of fishes.

Climate Variability and Change

Climate variability and change intensified in the AGL region with air and lake surface water temperatures increasing since the 1980s (**Fig. 4**). This has increasingly changed the aquatic habitat through fluctuations in lake levels, modification of wind speed,

Fig. 3 Kariba weed on Lake Kyoga (top panel) and water hyacinth on Lake Victoria (bottom panel) showing the influence of the weeds on inshore areas and apparent impact on lake use. Photographs from Fred M. Wanda (top panel) and personal field file (bottom panel).

circulation dynamics, production processes, stratification, loading and recycling of nutrients, and oxygen. This has affected especially those fishes in shallow lakes or shallow near shore areas of deep lakes and contributed to a shift in the composition of organisms to those that can tolerate the changed conditions (FAO, 2010; MacIntyre, 2012; Ogutu-Ohwayo et al., 2016).

Trends of the Drivers in Individual Lakes

The ecosystem drivers discussed above have contributed to alteration of the biogeography of the AGL at different rates depending on age and morphometry of individual lakes, the human population density in their basins, fisheries exploitation, land use change, and climate variability and change, but there are commonalities between the different lakes (Table 3). These have been accompanied by changes in the composition of fishes, fish species introductions and cage aquaculture to boost fish production of some lakes, changes in physical and chemical conditions and other biological factors, and proliferation of invasive weeds.

Lake Victoria

Lake Victoria is shared between Kenya, Uganda and Tanzania. It is the largest, and second youngest among the AGL (~400,000 years) but dried up and refilled about 14,300 years ago (Johnson et al., 1996). The lake has many papyrus-fringed bays in the west and rocky and sandy areas, especially in the south. It has open connection with many large rivers including

Fig. 4 Changes in air and water temperatures around the AGL between 1985 and 2010. Data adapted from Ogutu-Ohwayo R, Natugonza V, Musinguzi L, Olokokotum M, and Naigaga S (2016) Implications of climate variability and change for African lake ecosystems, fisheries productivity, and livelihoods, *Journal of Great Lakes Research* 42: 498–510, based on data from Sharma S, Gray DK, Read JS, et al. (2015). A global database of lake surface temperatures collected by in situ and satellite methods from 1985 to 2009. *Scientific Data* 2: 150008. <https://doi.org/10.1038/sdata.2015.8>.

Kagera, Katonga, Sio, Yala, Nyando, and Sondu-Miriu. Its outflow is through the Nile, the longest river in Africa, which runs through Lake Kyoga before flowing over Murchison Falls into Lake Albert at an elevation of 615 m amsl and traverses three countries (South and North Sudan, and Egypt) where its waters are highly valuable for irrigation before entering the Mediterranean Sea. The Murchison falls separates the Victoria/Kyoga system and Lake Albert and the fauna of the two systems are distinctly different and have been prevented from mixing by the falls. The Kyoga system has over thirty satellite lakes and shares a similar fish fauna with that of Lake Victoria (Ogutu-Ohwayo et al., 2013). The lake is relatively shallow, has been exposed to most of the ecosystem drivers discussed above, and provides a classical example of how these drivers have, altered the biogeography of the AGL.

The Lake Victoria basin has the highest human population density in the AGL region. It has intensive agricultural activities with high rates of deforestation and wetland degradation, the highest number of urban and peri-urban areas along its shores, and at least five hydropower dams on the Upper Victoria Nile (Table 3). There is extensive deforestation to open up land to agriculture in the lake basin and, in many places, gardens extend up to the edge of the lake (Fig. 5) exposing the lake to contaminants from the catchment area, and enhancing nutrient enrichment, sedimentation and increasing pollution and degrading the lake habitat.

Lake Victoria supports the largest freshwater fishery in the world that produces about one million tons of fish annually but this increased to this level after environmental changes that started in the late 1970s. The fishery directly employs about 200,000 people and up to 700,000 people along the value chain. The lake originally had > 500 haplochromine cichlids and 36 larger lake and riverine fish species (Graham, 1929). The commercial fishery originally comprised about twelve fish species dominated by two endemic tilapias (*O. esculentus* and *O. variabilis*), *Bagrus docmac*, *Clarias gariepinus*, and *Protopterus aethiopicus* while the rivers fisheries comprised *Labeo victorianus*, *Barbus* spp. and Momryrids. The native tilapias mainly inhabited near-shore areas (Graham, 1929) while the riverine species migrated up the rivers to spawn during rainy seasons and returned to the lake to feed (Cadwalladr, 1965). The stocks of the native tilapias and the riverine species were depleted by human exploitation following the introduction of more efficient gears and expansion of markets and their stocks had virtually collapsed by the early 1960s (Fig. 6).

Table 3 A summary of the key ecosystem factors discussed on different AGL and their status generated from literature quoted in this paper.

Key drivers	Victoria	Malawi	Tanganyika	Kivu	Edward	Albert	Turkana
Human population density/km ²	41–>500	11–100	11–500	41–500	41–100	11–100	2–40
Fish species diversity	> 500	~1000	~330	~28	~81	56	50
Changes in large native species	Collapsed	Collapsed	Declined	Had none	Persisting	Declined	Declined
Fish yield (metric tons)	1,000,000	44,000	200,000	10,000	17,000	180,000	9500
Number of fishers	200,000	56,000	45,000	6560	2000	40,000	8160
Number of introduced fish species	5	0	0	2	0	0	0
Cage aquaculture (no of cages)	12,086	53		208			
Land degradation (farming, deforestation, wetlands)	Rampant	Rampant	Moderate	Rampant	Limited	Moderate	High in Omo Delta
Urbanization (municipalities)	At least 9	0	2	1	0	0	0
Number of hydropower dams	> 5	~1	3	3	0	1	5
Status of oil and gas	None	Oil reserves in region	Oil reserves in region	Methane under development	Oil reserves in region	Oil under	development
Oil under development	Much	Little hyacinth	Little hyacinth	None	None	Much	<i>Prosopis juliflora</i> and water hyacinth
Invasive weeds	hyacinth					hyacinth	
Terrestrial game reserves	None	1	4	2	2	1	3
Temperature	Increased	Increased	Increased	Increased	Increased	Increased	Increased

Primary productivity/algal biomass	Increased	Decreased	Decreased				
Algal species composition	Shifted						
Invertebrate composition	Shifted						
Contribution of small pelagics to fish yield	45%	35%	65%	60%		80%	

Haplochromine cichlids formed about 80% of the fish biomass in the lake up to the 1980s (Kudhongania and Cordone, 1974). A trawl fishery was then introduced to exploit the smaller predominantly offshore demersal haplochromine species which were still abundant. This too was followed by a decline in catch rates of haplochromines from 1753 kg h⁻¹ in 1976 to 680 kg h⁻¹ in 1982 due to limited resilience of most haplochromine species to exploitation attributed to their limited distribution, as well as specialized breeding and feeding habits of individual species (Ogutu-Ohwayo, 1990).

The collapse of the native fishery led to introduction of Nile perch and four tilapias species to boost fishery production (Ogutu-Ohwayo, 1990). The stocks of the introduced Nile perch increased rapidly from the late 1980s onwards resulting in an increase in fishery yield from about 100,000 tons to about half a million tons annually by the late 1980s (Fig. 7). This was accompanied by a rapid decline in haplochromines which was attributed to predation by Nile perch and is estimated to have exterminated about 200 of the > 500 haplochromine species that inhabited the lake (Witte et al., 1992). During the same period, remnants of the native tilapias whose stocks had been drastically reduced by overfishing collapsed due to competition with the introduced Nile tilapia (Ogutu-Ohwayo, 1990). Although total fishery yield increased, the fishery of the lake became dominated by only three fish species; the two introduced species (Nile perch and Nile tilapia) and one native pelagic cyprinid, *R. argentea* whose importance increased to contribute about 60% to the biomass and 45% to commercial catches from the lake (Mangeni-Sande et al., 2019). Afterwards some haplochromines species especially two pelagic zooplantivorous species, *Yssichromis laparogramma*, and *Yssichromis pyrrhocephalus* increased in abundance (Kishe-Machumu et al., 2015; Fig. 7). These were able to increase through adaptive radiation involving extension of their distribution from offshore to inshore waters and expansion of their zooplankton diet to include insects and other larger prey (Kishe-Machumu et al., 2017).

There were other changes in biogeography of Lake Victoria associated with changes in environment which had been cumulative due to activities of the rapidly increasing human population since the turn of the 20th century (Hecky, 1993) but only manifested after the 1970s. These changes are thought to have been triggered by increasing variability and change in climate which altered wind regimes, circulation dynamics and made accumulated nutrients available to the production processes in the water column (Hecky et al., 2010) and could have been responsible for the increases in fishery yield. The concentration of phosphorus doubled, and silica decreased 10 times, algal productivity increased 5 times, the algal communities shifted from dominance of diatom species *Aulacoseira* spp. to blue green algae, stratification increased, and deep waters became anoxic. The zooplankton community shifted from

Fig. 5 Trees cut to open up land (A) and a garden extending up to the edge of the lake with marginal papyrus burnt (B) in the in the Lake Victoria basin. File photo by the author.

larger calanoid copepods to small cladocerans and cyclopoid copepods and the larger invertebrates by chironomid and chaoborid larvae and the prawn *Caridina nilotica* (Mwebaza-Ndawula, 1994).

It is during the late 1980s, that the water hyacinth (Fig. 3) infested lakes Victoria, Kyoga and Albert covering 60% of the shoreline of Kyoga and 18,000 ha of inshore areas of Lake Victoria (Twongo, 1996) apparently as a consequence of increased nutrient availability. The invertebrate communities under the water hyacinth mats was dominated by low oxygen tolerant types such as chironomids (Wanda et al., 2001), and the fish community by hypoxia-tolerant species, such as the lungfish. Later, the Kariba weed (Fig. 3) increased especially in the shallow Lake Kyoga, but the impact on aquatic biota has not been examined.

Cage aquaculture was introduced on Lake Victoria in 2006 to improve the fish supply deficit to feed the rapidly increasing human population. The highest number of cages in the AGL region is on Lake Victoria (Musinguzi et al., 2019) and will as it expands amplify the changes in biogeography of the lake if not well regulated. The number of hydropower dams along the Victoria Nile has also increased from one to five adding to alteration in biogeography of the river and associated lakes. The lake also has the highest number of urban and peri-urban areas along its shores most of which discharge their waste into the lake and contribute to nutrient enrichment. Other lakes in the region are going through a history similar to that of Victoria and have started manifesting similar symptoms and effects on biogeography of the lakes (Otu et al., 2011). The many changes associated with human activities have made Lake Victoria to be classified among the large lakes most highly impacted by human activities (Dobiesz et al., 2010).

Fig. 6 The decline and subsequent collapse of the originally important lake and riverine fisheries of *Oreochromis esculentus* (B) and, *Labeo victorinus* (A) fisheries of Lake Victoria. Redrawn from Ogutu-Ohwayo R (1990) The decline of the native fishes of lakes Victoria and Kyoga (East Africa) and the impact of introduced species, especially the Nile perch, *Lates niloticus*, and the Nile tilapia, *Oreochromis niloticus*. *Environmental Biology of Fishes* 27: 81–96.

Lake Malawi

Lake Malawi is the southernmost and the third largest of the AGL. It is shared by Malawi, Tanzania and Mozambique. It is the third deepest lake in the world and is meromictic with waters below 200 m permanently deoxygenated (Weyl et al., 2010). The major inflows include rivers Ruhuhu, Rukuru, Songwe, Dwangwa, Lilongwe, and Cobue. The outflow is the Shire River, which flows into the Zambezi that drains into the Indian Ocean. The northern catchment has steep landscape which decreases to the south and deforestation is rampant along the slopes. It has a high diversity of near-shore rocky and sandy habitats that have contributed to evolution of a high diversity of endemic fishes, especially cichlids (Fryer and Iles, 1972).

Fig. 7 The changes in commercial catch composition in Lake Victoria between 1959 and 2014 following establishment of Nile perch and Tilapias. Based on Lake Victoria catch statistics in NaFIRRI archives.

Lake Malawi is the most fish species-rich lake in the world with ~1000 fish species mainly cichlids, of which, 90% are endemic. The lake supports a fishery of about 44,000 tons annually, employing about 56,000 fishers and supporting livelihoods of > 1.6 million people (Weyl et al., 2010). Stocks of the three originally commercially important native tilapiine species locally known as chambo were, as for Lake Victoria, depleted through overfishing (Jamu et al., 2011) and the fishery has become dominated by pelagic species mainly *Engraulicypris sardella* which contribute up to 35% of the commercial catches. Introduction of a trawl fishery to exploit open water haplochromines was followed by their rapid decline (Turner, 1977). Nile tilapia, which contributed to displacement of native tilapias from lakes Victoria and Kyoga is used in aquaculture in the Lake Malawi basin and could further affect native tilapias if it gained access to the lake (Genner et al., 2013) and efforts should be made to avoid its entry into the lake. The lake is starting to be threatened by sedimentation, increased nutrient inputs especially phosphorus and the composition of phytoplankton is changing (Otu et al., 2011). The lake is also sensitive to climate change and has experienced a decline in lake levels (Kumambala and Ervine, 2010). Lake Malawi was the first AGL to which cages aquaculture was introduced to boost production and this is contributing to nutrient enrichment (Gondwe et al., 2011) and needs to be well managed.

Lake Tanganyika

Lake Tanganyika is the deepest of the AGL and the second deepest in the world. It is shared between Burundi, Democratic Republic of Congo (DRC), Tanzania and Zambia. It has the longest water residence time and is meromictic like Lake Malawi with water below 150 m having no oxygen (Salzburger et al., 2014). The main river inflows are Ruzizi (from Lake Kivu), Malagarasi and Kalambo, and the main outflow is the Lukuga River which is part of the river Congo system that drains into the Atlantic Ocean. Its entire western shoreline is very steep, which, together with its depth had contributed to it being classified among the large lakes least impacted by human activities (Dobiesz et al., 2010). The fish fauna of lakes Tanganyika and Kivu have with the exception of one species *Barinus mori* been prevented from mixing by rapids along River Ruzizi. The water level of the lake has, during geological times, dropped to levels which have split it into two lakes (Salzburger et al., 2014). This and the high diversity of rocky habitats and sandy near-shore habitats have contributed to evolution of high diversity of fishes including open water pelagic fish species, cichlids fishes and molluscan fauna (Beadle, 1962, 1981).

Lake Tanganyika is the oldest among the AGL and the fish fauna and other organisms that were of a riverine origin have fully become lacustrine with four endemic *Lates* species and two endemic clupeids. In this respect, it's regarded as having the most mature fish fauna and other organisms among the AGL (Coulter, 1988). The lake had 80 non-cichlid species of which 60% were endemic and about 250 cichlid species of which 99% were endemic. The fishery yield from the lake is ~200,000 tons annually, employing 45,000 fishers and providing 25–40% protein to about one million people (FAO, 1999). It has an ornamental fish trade. The native fishery that was originally dominated by four large endemic *Lates* species and two small sardines has changed and is dominated by one pelagic *Lates* species and the two pelagic sardines. The lake had many endemic invertebrate species (83 snail species, 65 endemic), (11 bivalves, 8 endemic), and (200 crustaceans, > 50% endemic) but their current status is not clear.

Climate warming is thought to have affected mixing dynamics of Lake Tanganyika and contributed to a decrease in primary productivity by 20% and fisheries yield by 30% (O'Reilly et al., 2003). Sedimentation is thought to be affecting stocks of inshore haplochromines stocks (Cohen et al., 1996) and development of oil and gas resources which have been discovered in the basin pose additional future threats. There are four terrestrial national parks (Ruzizi, Gombe, Mahale, and Nsumbu) around the lake which partly shield the lake from environmental degradation. Cage fish farming has started on the lake and is expected to grow but given the morphometry of the lake where wastes are expected to accumulate in deep waters, this may have limited impact on biogeography. However, it still needs to be well managed as cages are normally located in shallow near shore areas which are critical fish breeding and biodiversity areas.

Lake Kivu

Lake Kivu is at the highest elevation of 1460 m amsl among the AGL and is shared between DRC and Rwanda. It originally drained northward into the Nile sub-basin but this was reversed following volcanic eruption that formed Virunga Mountains. It flows into Lake Tanganyika over an elevation of 670 m. It is one of the smallest but the third deepest among the AGL. It has a hilly catchment and steep shoreline which is densely populated with high rates of deforestation and a potential source of siltation and localized eutrophication. It is meromictic with a shallow eutrophic zone. The water below 63 m has large quantities of methane and CO₂, and about 99% of the deep water is permanently deoxygenated.

Lake Kivu has the most impoverished fish fauna among the AGL (Salzburger et al., 2014) with 28 species including *Barbus*, *Clarias*, and *Tilapia* species with only 15 haplochromines species, 50% of which are endemic. Consequently, the Lake Tanganyika sardines (*L. miodon* and *S. tanganyikae*) were introduced into the lake in 1959 to enhance fish production. The lake produces about 10,000 tons of fish annually mainly of the sardine fishery supporting about 6600 fishermen (Snoeks et al., 2012). Among the two sardines, it is the predominantly deep water *L. miodon* which became well established and contributes most to the fishery of the lake. The lake has the highest number of fish cages in the AGL region after Victoria and cage fish farming is expected to become a major source of fish on the lake. However, as in the case of Lake Tanganyika, this may not have negative impacts due to the lake's morphometry but should be well planned and managed. The lake has large quantities of methane which is exploited for energy and this needs to be monitored and managed to reduce potential negative impacts. There are also a number of emerging urban areas along its shores and in its basin which will in the long run affect its environment and need to be well managed.

Lake Edward

Lake Edward is located in the Western arm of the rift valley. It is part of the Nile drainage basin draining into Lake Albert. It is the smallest of the AGL and is shared between DRC and Uganda. It has very steep shoreline along the DRC shores. The main river inflows are the Nyamugasani from the southwest and the Ishasha, Rutshuru and Bwindi from the south and is connected to Lake George through a 36 km Kazinga channel. The outflow is via River Semliki to Lake Albert where the fish fauna of two lakes have been prevented from mixing by the Semliki rapids. The lake experiences prolonged stratification and anoxic conditions below 80 m.

Lake Edward has ~81 fish species, of which 60 are cichlids, 92% of them endemic. The fish species composition of the lake has not changed much (Crespi and Ardizzone, 1995) apparently because of its location among national parks (Virunga and Queen Elizabeth) which are protected areas and have partly shielded it from the anthropogenic impact experienced by the other AGL. Similarly, the water quality and productivity of the lake have remained fairly stable over time with no major shifts in nutrient fluxes, phytoplankton species composition or chlorophyll-a. The fishery yield from the lake is about 17,000 tons supporting about 2000 fishers. There are, however, proposals to improve the fishery through exploitation of the abundant pelagic haplochromines. As reported for lakes Victoria and Malawi, haplochromine cichlids are not resilient to heavy commercial exploitation and this could result in a decline in their stocks and needs to be well regulated. There are prospects for cage fish farming and salt mining on the lake which could provide alternative livelihoods of people around the lake whose activities are restricted due to being in a protected game area.

Lake Albert

Lake Albert is the shallowest of the AGL and is shared between Uganda and DRC. It is monomictic, mixing completely once a year. The main inflows are River Semliki from Edward and the Victoria Nile from Lake Victoria via Kyoga and connects to the Albert Nile with which it shares a nilotic fish fauna finally draining into the Mediterranean Sea via the Nile. The water from the Victoria Nile on the north-eastern corner of the lake does not mix much with that of the rest of Lake Albert before exiting to the north but plays an important role of stabilizing the lake water levels.

Lake Albert has relatively low fish species diversity with 56 fish species but with a relatively higher number of non-cichlids compared to other AGL, and unlike other AGL, has only six haplochromine species, two of them endemic (Wandera and Balirwa, 2006). It is the third most productive lake among AGL yielding about 180,000 tons of fish annually supporting about 40,000 fishers. The larger native inshore species such as *Citharinus citharus* and *Distichodus niloticus* were depleted in the early 20th century by the beach seine fishery (Worthington, 1929). Stocks of other large species have, as in other AGL, declined and the fishery has become dominated by two pelagic clupeids (*Neobola bredoi* and *Brycinus nurse*) which contribute about 80% of the commercial catches. Despite this, Lake Albert is the only AGL which has sustained a multi-species fishery, mainly of non-cichlid species and this need to be well managed.

Water temperatures have increased by 0.5 °C and total phosphorus and nitrate have decreased below historical records (Lehman et al., 1997). Murchison Fall National Park that supports tourism is located along its north-eastern borders. Large oil deposits have been discovered in the lake and its basin and exploitation is at an advanced state. This is a major environmental threat to the lake and its biotic communities and should be closely monitored and properly managed to avoid negative impacts on critical habitats of the lake. There are also prospects for cage fish farming which could provide additional sources of fish.

Lake Turkana

Lake Turkana is the northernmost of the AGL, and the world's largest permanent desert and alkaline lake. It is the remotest of the AGL and is shared between Kenya and Ethiopia. It lies at the lowest altitude of 360 m amsl of the AGL in a closed basin in the Eastern Rift Valley. The eastern and southern shores are bounded by rocky margins, and the western and northern shores by sandy sediments.

Lake Turkana has a native nilotic fish fauna similar to that of Albert with ~50 fish species of which 11 are endemic (Beadle, 1981). Its fish stocks and fisheries are similar to that of Albert. The lake has the lowest fish production of ~9500 tons among the AGL supporting about 8160 fishermen (Avery, 2013) but the contribution of small pelagic cyprinid species that contribute most to Lake Albert fishery and are known to occur in Lake Turkana is currently is not known.

Lake Turkana is the most threatened of the AGL partly because of its location in an arid region but more importantly due to construction of dams and planned irrigation schemes along the Omo River which affects the water levels (Avery and Tebbs, 2018; Gownaris et al., 2015). The Omo River provides over 80% of the lake's annual freshwater input and associated nutrients. Development of the dams and irrigation schemes along the Omo River is reducing the flow of water and impacting the water level in a manner similar to what happened on Lake Chad and could turn the lake into the Aral Sea of Africa. For instance, when the Gibe III reservoir was filled in 2015/16, the water level of the lake dropped by 2 m and the irrigation schemes in the Lower Omo are expected to remove an additional 50% of the water. It is predicted that this will cause the lake level to drop by 15 m with enormous consequences on its ecology (Avery and Tebbs, 2018) and need urgent action to avoid it. There are also developments of oil in its western shore which need to be developed in a manner that does not impact negatively on the lake.

Synergy and Lessons From Other Lakes

The changes in biogeography of the AGL have occurred in other lakes in the AGL region, Africa and the world. Lakes such as Kyoga, Mweru and Rukwa which are traditionally not classified among AGL and satellite lakes (e.g., Nabugabo and Wamala in the Lake Victoria basin), about fifteen small lakes in the Eastern arm of the rift valley (Fig. 1) have gone through similar alterations in the lake habitat and fisheries. Lakes Kyoga and Nabugabo have undergone changes in their fisheries and environment similar to that of Lake Victoria (Ogutu-Ohwayo et al., 2013). Lake Chilwa has gone through episodes of drying up with concomitant changes in its fauna and flora associated climate variability and change. Even manmade lakes in the AGL region such as Lake Kariba have experienced similar changes in their environment, biotic communities and fisheries.

Lake Chad in Northern Central Africa which, like Lake Turkana, lies in a closed basin shrunk by 90% between 1960 and 1990 due to dam construction, excess extraction of water for irrigation from the rivers that flow into the lake, and climate change and this was accompanied by a decrease in the number of fish species from about 40 to 15 (Lévêque, 1995). The Aral Sea, in Russia, which was once the fourth largest lake in the world has shrunk by 90% due to diversion of water for irrigation of cotton farms (Whish-Wilson, 2002). Although there are efforts to improve the hydrological conditions of the Aral Sea, the waters are so heavily polluted by the chemicals applied on cotton farms that the fish and the water might never again be suitable for human consumption and use. The resources and environment of the North American Laurentian Great Lakes were also initially shaped by rapid human population growth during the early 19th century due to deforestation and conversion of land to agriculture (Beeton, 1965). The lakes have also gone through periods of nutrient enrichment especially of phosphorus, invasive species especially of the Sea lamprey (*Petromyzon marinus*) which decimated the fish stocks. These alterations have been improved through management efforts and these experiences can be useful to other lakes going through the same history such as those of the AGL region.

Lake Baikal which is the oldest (25–30 million years), the world deepest (1642 m) and probably the world's cleanest lake could have served as a good example of protecting a lake from alterations due to anthropogenic impacts but has started experiencing changes in its environment. Some potential threats to the lake such construction of a paper mill and an oil pipeline, and plans to extract and export water from the lake that were threatening the health of the lake had been prevented. The lake has been designated a UNESCO heritage site. However, it has been invaded by an invasive plant *Elodea canadensis* introduced in the 1950s (Mackay et al., 2002), and is increasingly becoming an important tourist destination and these developments will overtime affect the lake as they intensify and need to be addressed early enough.

Resilience and Persistence

Overall, the impacts of human activities on lakes has been observed to vary with lake morphometry and human population density in their basins (Dobiesz et al., 2010). Large, deep lakes such Tanganyika, Baikal, and Superior, with lower population densities in their basins have been less affected by anthropogenic factors than shallower lakes with high population density and intense agriculture and land use alterations such as Victoria, Michigan and Ontario. Endorheic lakes that lie in a closed basins such as Turkana, Chad and the Aral Sea are highly susceptible to human activities and need special attention.

Small, short-lived fish species that inhabit less structured open-water environment are more resilient than those that are restricted to shallow lakes or shallow inshore areas of deep lakes. Examples include the small short lived small pelagic cyprinids (Fig. 8) whose stocks have increased in importance, and contribute the largest quantity of fish landed in most of the AGL (Table 3; Fig. 9). Most of the cichlid have been depleted but a few have adjusted their life history characteristics and persisted. The species that have persisted under anthropogenic stressors are likely to form future fisheries on the AGL under changing anthropogenic stressors.

Fig. 8 Lake Tanganyika sardine on Lake Kivu. Courtesy, Modesta Medard.

Fig. 9 The changes in contribution of small pelagic clupeids to commercial catches in lakes Victoria, Albert and Kyoga, illustrating the increase in pelagic species in the AGL. The figure is based on fish catch statistics of Uganda.

Understanding the factors that have determined resilience and persistence is important in predicting the future biogeography, especially of fishes under increasing human footprints. Among the tilapia species, it is only the Nile tilapia which has persisted in most of the lakes and even displaced other tilapia species in those lakes to which it has been introduced (Ogutu-Ohwayo, 1990). The success of Nile tilapia is associated to its life history attributes, including early maturation, a broad food spectrum, and a wide habitat range (Fryer and Iles, 1972). It can alter its fecundity under stressful conditions, and can digest blue green algae which have increased in most lakes with eutrophication and can even feed on invertebrates and other fishes when their preferred algal food becomes scarce (Moriarty and Moriarty, 1973; Njiru et al., 2007; Natugonza et al., 2015). These attributes have contributed to the success of Nile tilapia becoming one of the most important commercial fish species in capture fisheries and aquaculture in the AGL region and other parts of the world (Ogutu-Ohwayo et al., 2016). The pelagic fishes, whose populations have increased, have a very fast growth rate, are not habitat restricted and produce pelagic eggs. These small fishes are normally valued less commercially than the larger species. They are, however, be sun dried which has limited impact on the environment and eaten whole, and have high in protein, micronutrients such as calcium, iron and zinc, and vitamins that are essential for healthy living (Hicks et al., 2019). Their nutritional value especially in combating malnutrition among the poor rural communities exceeds their monetary value and should be factored in assessment of their value.

Table 4 A summary of potential management interventions for the different factors that affect biogeography of AGLs and their relative intensity derived by the authors from the information in this review (+++ = high intensity; ++ = moderately intensity; + = little intensity; 0 = not intense).

Management interventions	Victoria	Malawi	Tanganyika	Kivu	Edward	Albert	Turkana
Mobilize and share management data and information	+++	+++	+++	+++	+++	+++	+++
Network institutions to harmonize information and data	+++	+++	+++	+++	+++	+++	+++
Translate harmonize information and data into national policies	+++	+++	+++	+++	+++	+++	+++
Strengthen linkages between research and management institutions	+++	+++	+++	+++	+++	+++	+++
Develop sustainable funding mechanisms	+++	+++	+++	+++	+++	+++	+++
Control human population growth rates	+++	+++	+++	+++	++	+++	+
Promote sustainable land management (SLM) practices, and urban planning	+++	+++	+++	+++	++	+++	+
Reduce deforestation, sedimentation, urban wastes, nutrient enrichment, and pollution and promote afforestation	+++	+++	+++	+++	++	++	+
Incorporate impacts of dams in their planning, design, and operation	+++	+	+	+	+	++	+++
Extract oil and gas in a manner that does not harm aquatic biodiversity and the environment and monitor impacts	+	++	+	+++	+++	+++	++
Control fishing effort, gear types, sizes and numbers, set closed seasons and promote recovery of depleted fishes	+++	+++	+++	+++	+++	+++	++
Develop plans to specifically manage fisheries small pelagics	+++	+++	+++	+++	++	+++	+
Identify and conserve critical habitats for aquatic biodiversity and set up aquatic protected areas	+++	+++	+++	+++	+++	+++	+++
Develop alternative livelihood options specific to fishers	+++	+++	+++	+++	+++	+++	++
Prevent spread of invasive fish species	+	+++	+++	+	+++	+++	+++
Monitor, control and prevent spread of invasive weeds (water hyacinth and Kariba weed)	+++	++	++	++	++	++	+++
Develop best management practices for cage aquaculture through proper planning, siting and production practices	+++	+++	+++	+++	+++	+++	+
Investigate impacts of climate change on aquatic systems, fisheries and livelihoods and develop adaptation and mitigation measures	+++	+++	+++	+++	+++	+++	+++

Management of the Drivers

The above review shows that biogeography of the AGL and other lakes in the world is being altered and is expected to continue to change due to demands of an increasing human population. There is, therefore, need for management measures to regulate the alterations. Some of the initial actions needed based on information discussed in this paper are summarized below and in [Table 4](#) but should be continuously updated with new knowledge and data. Many of the alterations and the required actions are common to the AGL and other lakes in Africa and the world although they differ in intensity between some lakes. Thus, the need to network and share information nationally, regionally, continentally and globally. The key observations and actions which could serve as a baseline in management of the AGL discussed in this article and were also agreed upon during the African Great Lakes Conference of May 2017 ([Doran et al., 2018](#)) are as follows:

- The AGL basins have high human population densities and growth rates, driven primarily by high birth rates. Population growth rates should be moderated through increasing access to family planning and reproductive, maternal and child health services.
- The AGL have increasingly become nutrient enriched from unsustainable land use practices conversion of land to agriculture, deforestation, degradation of wetlands and riparian zones and urban wastes. Sustainable land management (SLM) practices, including protection of forests wetlands and riparian zones, should be promoted to reduce nutrient loading and siltation to protect aquatic ecosystem health. Increase in agricultural productivity should be done through improved and environmentally sustainable farming practices including proper use of fertilizers and pesticides to reduce pressure on bringing poor productivity land into agriculture.
- Most of the shorelines and catchments of the AGL region are becoming urbanized. Urban planning should be applied to minimize pollution of the lakes from industrial and urban wastes. Point and non-point sources of pollution should be identified, and measures taken to manage them.

- (d) Hydropower dams have and continue to be constructed along the rivers flowing into and out of the AGL to provide power required for development but affect the river and lake ecosystems and biodiversity. The impacts of dams on aquatic ecosystems and biodiversity should be determined and mitigation measures included in their design, construction, and operation.
- (e) Oil and methane have been discovered in some lakes and their basins and exploitation is either under way or taking place. Environmental and Social Impact Assessments (ESIAs) should be conducted prior to extraction, and mitigation measures put in place during exploitation.
- (f) There are protected areas on land around some lakes such as national parks but very few lake-based protected areas. Critical habitats for conservation of aquatic biodiversity should be identified and protected.
- (g) Stocks of many fish species of > 20 cm have declined and some completely collapsed due to high fishing pressure, use of destructive fishing gears and methods, invasive species, habitat degradation, and limited resilience. Fishing capacity should be controlled through regulation of gear types, sizes, and numbers, and limiting access. The factors that contribute to decline of some and persistence of other fishes should be determined and incorporated in management measures. Efforts should be made to promote recovery of stocks of depleted large fishes.
- (h) Small pelagic species have increased and dominate fish stocks in many of the AGL amidst multiple stressors. The causes of increase in stocks of small pelagic species should be determined and specific management plans developed for them.
- (i) Fishers have limited livelihood opportunities which contributes to their over-dependency and overexploitation of fisheries. Alternative livelihood options should be developed specifically for fishers to reduce dependency on wild fish stocks.
- (j) Introduction of fish species has, despite in some cases increasing fish production, contributed to depletion of other fishes. Measures should be taken to protect the lakes from introduction of non-native fish species. Restorations should be made only in those lakes with an impoverished fish fauna.
- (k) Cage fish farming has started on many lakes in the AGL region and has potential to reduce the deficit in fish supply due to declining stocks of wild fish stocks, but has socio-economic and environmental challenges. Best management practices for cage fish farming should be developed through spatial planning, site selection, production and market practices, securing the environment, and effective policies.
- (l) Invasive weeds such as water hyacinth (*Eihhornia cresspes*) and the Kariba weed (*Salvinia molesta*) are increasingly becoming a problem in the AGL region. The occurrence, population dynamics, causes of proliferation and impacts of the weeds should be determined and appropriate control measures developed and implemented.
- (m) Temperatures of the AGL region are warming due to human induced climate change, and are affecting aquatic productivity, and shifting aquatic species to those that can adapt to the changed conditions. The impact of climate change on aquatic life, fisheries and livelihoods should be investigated and adaptation and mitigation measures put in place.
- (n) There is considerable information and data for addressing the issues affecting the AGL and their basins but are scattered, sometimes in forms that are not user-friendly, and in many cases not accessible. There is a need to mobilize, package and share information and data and to make it readily accessible in forms that can be used by a wide range of stakeholders.
- (o) All the AGL are shared by more than one country but their management takes place at national levels. Management actions should be developed and harmonized jointly by countries sharing each lake, and adapted for implementation by national governments. Institutions of countries sharing a lake should be networked to harmonize management measures. These should then be translated into national policies for implementations. There should be a network of countries sharing the different AGL to share experiences.
- (p) Many of the research, management, and community institutions working on the AGL are uncoordinated and often donor driven with short life spans. These should similarly be networked to share information to reduce transaction costs. Longer term solutions to coordinate, strengthen, and fund research and management of these critical resources and ecosystem services of the AGL are needed. These should be coordinated through networking of institutions nationally, regionally, continentally, and globally.
- (q) Funding for collection and implementation of management information and data within and across lake basins is inadequate and insufficient to sustain the ecosystem health and services of the AGL. Addressing issues collectively with collaborative funding mechanisms would reduce transaction costs.

Institutional Requirements

Sustainable management of the AGL will require appropriate institutional arrangements to coordinate generation and mobilization of information and data to guide development of policies for management of the lakes and their basins. Management measures are normally taken by national governments at national level. Since most of the AGL are trans-boundary and shared by more than one country, the measures to be implemented at national level need to be harmonized between the countries sharing each lake. The harmonized measures can then be adapted and translated into policies for implementation at national level.

Some of the AGL have formed specific regional institutions to coordinate collection of information and data and harmonizing management measures between the nations sharing a lake such as the Lake Victoria Fisheries Organization (LVFO) and the Lake Victoria Basin Commission (LVBC) on Lake Victoria, The Lake Tanganyika Authority (LTA) on Lake Tanganyika, and The Lake Kivu and Rusizi/Ruzizi River Basin Authority (ABAKIR) on Lake Kivu. Some of the AGL such as Lake Edward, Albert, and Turkana

do not have regional organizations. Since many of the management issues facing the lakes are similar, it will be beneficial to network to develop and share information, data and experience between those organizations with regional institutions. These could then network with institutions around those lakes without such organizations to form an African Great Lakes Network. These arrangements have worked around other shared lakes in Africa such as Lake Chad which has a Lake Chad Basin Commission (LCBC) and at international level such as Great Lakes Fishery Commission and International Joint Commission (IJC) on the Laurentian Great Lakes. Besides many of the issues facing the lakes of the world are similar. It will, therefore, be beneficial to develop networks between the lakes of the world at national, regional, continental and global levels to share information and data, and management experiences. These networks if developed will improve coordination of efforts to mobilize information and data for management of the lakes. Research, management, and community institutions could form similar networks at national, regional, continental and global levels. These arrangements could improve capacity and reduce transaction costs for generation, mobilization of information and data, and implementation of management measures for conservation, development and management of lakes at national, regional, continental and global levels.

Conclusions

The resources of the AGL and their basins are highly valuable for ecosystem health and livelihoods. These resources are changing and will continue to change with the rapidly increasing human population. Most of the lakes are trans-boundary and many of the problems facing them are common among the lakes. There is need to form networks at national, regional, continental and global levels to continually monitor the changes in biogeography and their drivers, and to generate and share information and data to guide policies for development and management of the habitat and resources of the lakes to avoid reaching catastrophic levels and share expertise.

Acknowledgments

We are grateful to colleagues at NaFIRRI who provided input in this article and to Elsevier for inviting us to prepare it and to R.E. Hecky for construction comments on the original draft. This work was particularly inspired by the process set up by the African Great Lakes Conference of May 2017 that was organized by The Nature Conservancy and supported by the African Great Lakes Conservation Fund administered by the Nature Conservancy with funds from John D. and Catherine T. MacArthur Foundation to strengthen collaboration between AGL and by a request by the International Association of Great Lakes Research (IAGLR) to the lead author to develop modalities for strengthening collaboration between the Great Lakes of the world.

Abstract

If nutrients and a carbon source are available, life as we know it can actively reside nearly anywhere liquid water exists—even glacier ice and snow (Zawierucha et al., 2015). Just as with tropical rainforests, temperate grasslands, and polar tundra, the worldwide collection of glacial ecosystems residing on permanent freshwater ice can be considered as a biological biome (Anesio and Laybourn-Parry, 2012). In fact, all kingdoms of life (Ruggiero et al., 2015) have been found living on glacier surfaces, a land cover that extends over $1.6 \times 10^7 \text{ km}^2$ (Williams Jr. and Ferrigno, 2012), or 10% of the Earth's surface. The presence of these organisms living on glaciers leads to melting, and the melt-water they create is necessary for their existence, making the glacier biome important from a global warming perspective (Ganey et al., 2017). While all of the world's glaciers have much microbial life in common, especially single-celled algae, the taxonomic orders of glacier-dwelling macro-invertebrates differ across continents.

Part of Earth's cryosphere, glaciers, icefields, and ice-sheets are freshwater bodies of ice covering mountains and polar regions. Williams Jr. and Ferrigno (2012) report that ice covers most of Antarctica ($1.2 \times 10^5 \text{ km}^2$) and Greenland ($1.8 \times 10^6 \text{ km}^2$) as well as parts of North America ($1.2 \times 10^5 \text{ km}^2$), Asia with its Himalaya ($1.2 \times 10^5 \text{ km}^2$), the Andes of South America ($2.5 \times 10^4 \text{ km}^2$) especially Patagonia ($2.2 \times 10^4 \text{ km}^2$), Iceland ($1.1 \times 10^4 \text{ km}^2$), Europe ($5.8 \times 10^3 \text{ km}^2$), and New Zealand ($1.2 \times 10^3 \text{ km}^2$). These long-lasting bodies of ice form when—on average—the amount of snow that falls exceeds the amount that melts each year (Benn and Evans, 2010).

Glaciologists divide glaciers into three zones based on melt rate relative to snowfall: an upper elevation accumulation zone, where snowfall exceeds melt; a low-elevation ablation zone, where melt exceeds snow accumulation; and the equilibrium line altitude (ELA) between them. This transition zone can be extensive on flat glaciers and icefields. From a biological perspective, the ELA is richest in obligate glacier biota (Takeuchi, 2001, 2013), with both aquatic species (Kaczmarek et al., 2016) found in small, glacier-ice melt pools (Fig. 1) called cryoconite holes (Wharton et al., 1985), and snow and ice dwelling species (Takeuchi, 2001) found on frozen surfaces. The ablation zone is next richest, and includes non-glacier obligate taxa. Although disturbed by extreme rain events (Zawierucha et al., 2019) and rapid melting, the ablation zone is near off-glacier sources of nutrients and life. The upper accumulation zone is a veritable desert despite its snow (Shain et al., 2016) due to lack of melt.

Because liquid water is necessary for life, only where liquid water is present on glaciers can active, respiring life reside (Hodson et al., 2008). This resident, psychrophilic (from the Greek “psukhros” and “phylos” meaning cold-loving) life, usually microbial, may inhabit the glacier's surface (supraglacial), its interior (englacial; Hamilton et al., 2013), or even water between ice and basal bedrock (subglacial), where anaerobic subglacial microbes act as an important source for methane in Antarctica (Wadham et al., 2012) and elsewhere (Boyd et al., 2010). While necessary, liquid water is not sufficient to sustain life. Nutrients, too, such as nitrogen, phosphorous, and potassium (NPK) are needed, as well as a carbon source. Although englacial and subglacial life exists, this biome entry considers only surficial life as seen by a hiker or skier visiting a glacier during the melt season, when liquid water makes life most abundant.

A Glacier Walk

On a sunny late July day, a group of hikers ascends a glacier overlooking the Gulf of Alaska and draining the Harding Icefield (Fig. 2). The hikers leave the world of multicellular plants and warm-blooded animals behind as they step off a terminal moraine, the accumulated rocky debris marking the glacier's toe, and move onto the melting ice and snow of the ablation zone (Benn and Evans, 2010). The abundant blue wavelengths of light from the noon-day sun are not absorbed by water or ice, but instead reflected,

Fig. 1 Cryoconite Holes: (A) Rotifer and (B) Tardigrade.

Fig. 2 Coastal Alaskan glacier biota: (A) Ice algae, (B) Collembola, (C) Chugach ice worm showing curved setae, and (D) Snow algae.

giving dense glacier ice (where pressure has removed the air bubbles) its deep blue color. The hikers find the bare ice slippery. To move up-glacier they tread across the natural traction afforded by surfaces dusted in cryoconite (Takeuchi, 2001), a mélange of sediments, wind-blown detritus, and even living and dead microscopic psychrophiles (cold-loving organisms). Stepping past small, meltwater cryoconite holes in the bare ice, the hikers don't realize that each hole is a tiny microcosm of aquatic microbes and microscopic animals (Fig. 1), like rotifers and tardigrades (Zawierucha et al., 2015). Elsewhere, water drains quickly from red-colored snows and purple-tinged rugosities where single-celled algae and cyanobacteria thrive (Takeuchi et al., 2019).

The Ablation Zone

Insolation smooths ablation ice that is clean of debris but roughens the ice when the sun's erosive action is accelerated by dust, mineral particles, and ice algae (Cook et al., 2015). All of these light-absorbing particles darken the glacier's surface, reduce its albedo (reflective value), and so add solar energy to the glacier surface. In fact, most melting on glaciers comes not from warm air temperatures, but from absorbed radiation (Box et al., 2012).

While the tinkle of a thousand tiny rivulets signals melt, even in summer freezing occurs daily and so water, paradoxically, often limits life in this environment literally made of water. The icy nature of glaciers challenges life in other ways, too. Nutrients are sparse and frozen within ice and snow crystals, unavailable to life without melting. And without the microbial equivalent of sunscreen, blinding over-illumination can damage microbes' photosynthetic apparatus as readily as it can snow-blind a hiker without sunglasses.

The ELA

As they approach the snowline marking the ELA, the hikers stop to rope themselves together as protection against crevasse falls. Tying into the safety line, one hiker notices a few thread-like objects a couple centimeters long protruding from the icy walls of a meltwater pool. These “threads” are individuals of the North American glacier ice worm, *Mesenchytraeus solifugus* (Annelida: Oligochaeta: Enchytraeidae), a small, black annelid that looks like an earthworm but lives its life on glacier ice and snow (Shain et al., 2001). Their curved setae along their bodies help them cling to slippery ice.

Roped together, the group clomps over the ice wearing metal crampons. A hiker kicks over a small, flat rock, scraped off a mountain, uncovering hundreds of tiny “snow-fleas” hiding from the sun, but now exploding in all directions like a cloud of dust. These insects of the order Collembola are also called springtails. They can be very abundant on glacier surfaces (Eisenbeis and Meyer, 1999) and cryoconite pools all around the world.

Soon, patches of snow coalesce into snowfields that cover the hard glacier ice. In the hot sun, the snow is wet, and suncups (Vimercati et al., 2019) form with red-colored snow on their sides and bottoms. The hikers stop. One bends over and brings a handful of red snow close to her face to inspect it. The soggy snowball smells fruity.

“That’s watermelon snow,” says a companion. “It’s colored by algae.” Known since the 4th century BCE, watermelon snow was seen under the earliest microscopes to be colored red by living organism. The hikers shuffle through larger and larger patches of red snow, eventually finding themselves surrounded by a vast red snowfield. On glacier-dominated landscape adjacent to the Gulf of Alaska, watermelon snow can cover from tens to hundreds of square kilometers (Takeuchi et al., 2006; Ganey et al., 2017). The Alaskan snow algae living on glaciers of coastal mountains benefit from marine-derived nutrients blown-in from the stormy North Pacific, and in turn the algae feed glacier animals in the billions: ice worms and snow-fleas graze on snow-algae (Goodman, 1971).

The Accumulation Zone

The hikers stop to camp. As the sun drops below the horizon, the temperature cools and the previously wet snow forms a firm crust preventing ice worms that spent the day a meter below the surface protected from the sun from surfacing (Dial et al., 2016). Like other life on the glacier, the campers need water. They light their camp stove and melt snow for hot drinks and dinner. In the morning, the sun spills across the glacier’s surface but the surface crust remains frozen. It will not soften until midmorning, but already algal cells are absorbing sunlight to melt the snow they contact. The hikers continue upward, picking their way past crevasses. Climbing higher into cooler air, the melt-crust thins, then disappears in the accumulation zone. At these higher elevations, the hikers stand in snow virginally white and powder dry: there is no life where perpetual cold prevents the formation or liquid water.

Glacier Life Around the World

This walk could be repeated across glaciers throughout the glacier biome: past cryoconite holes full of microbes and microscopic animals and purple-tinted bare-ice, into red snow and then beyond to the accumulation zone, where no resident life is found. On glaciers of the wetter mountains of the Greater Himalaya (Fig. 3), New Zealand, and South America’s Patagonia (Fig. 4), animals as big as Alaska’s ice worms live. In glacial pools of eastern Nepal, hikers might see larvae of the Himalayan flightless midge (Insecta: Diptera: Chironomidae), *Diamesa de novo* (Kohshima, 1984), a fly that crawls across the bare ice and snow to find mates, or even the rare Tibetan ice worm, *Sinenchytraeus glacialis* (Annelida: Oligochaeta: Enchytraeidae).

In similar habitats on New Zealand’s South Island, keen naturalists could spot a different midge, *Zelandochlus latipalpis*, (Odell, 1956) with flightless males but winged females. In the meltwater pools of South America’s southern Andes, a lucky mountaineer might find a Patagonian dragon, *Andiperla willinki*, (Vera et al., 2012), a flightless stonefly (Insecta: Plecoptera: Gripopterygidae). At the apex of the most complex food-web of all our planet’s glacier ecosystems, the Patagonian dragon feeds on other minuscule animals such as collembola, rotifers, and tardigrades.

Elsewhere on Earth’s icy reaches—Greenland (Fig. 5), Svalbard, the Alps, Siberia, Antarctica—no flightless insects, nor glacier worms, nor other macroinvertebrates have yet been discovered; just microbes using solar energy to melt snow and ice crystals for water and the nutrients bound within. Antarctic and Greenland ice sheets (GrIS) rarely have watermelon-snow, even near the coasts (Williamson et al., 2018). However, a 25,000 km² “dark-zone” covering the west-central GrIS is tinted purple and gray by dense populations of ice-algae (Ryan et al., 2018). Unlike southern Alaska, Greenland experiences relatively light snowfall and a deeper cold, garnering its reputation as a “polar desert.” Similarly, no ice-dwelling annelids or insects larger than collembola have been discovered in Antarctica, Iceland, Europe, or Siberia. Consistent with the ecological principals of island biogeography (MacArthur and Wilson, 1967) and the latitudinal gradient of biodiversity, the small “islands” of European and tropical ice (such as Africa and Papua New Guinea) and the extensive, polar ice-sheets of Greenland and Antarctica have few species. It is the relatively warm, near-freezing glaciers of the temperate latitudes and wet subtropics, where limiting nutrients are blown-in as ocean aerosols, that support the most life. However, as the climate increasingly warms, glaciers, especially small ones, are lost and with them their unique biodiversity (Zawierucha and Shain, 2019).

Glaciers, Icefields, and Ice-sheets as Habitats for Life

Glacier algae solve the problems of frozen water, ice-bound nutrients, and blinding light with pigments. And because these pigments absorb solar radiation, Japanese (Takeuchi et al., 2015), American (Ganey et al., 2017), European (Stibal et al., 2017), and United Kingdom (Cook et al., 2017) scientists working on glaciers from the Arctic to the Antarctic to the high Himalaya increasingly identify microbes as responsible for more melt than any other glacier surface particle, including dust and potent black carbon (Stibal et al., 2017). Unlike the cold geophysics of non-living particles, the biological imperative for living organisms to survive and reproduce leads natural selection to favor those colors most conducive for melt (Dial et al., 2018) while avoiding overheating.

The color we see in an object is determined by the wavelengths of light reflected. The colors unseen in an object are the wavelengths absorbed, with the absorbed radiant energy converted to heat. Purple, blue, green, yellow, orange, and red fill the visible spectrum between damaging ultraviolet and water warming infrared. Sunlight arrives at Earth's surface mostly as blue and green wavelengths. Red and purplish-colored algae absorb these wavelengths, convert them to heat and use the energy to melt ice and survive in a frozen environment.

So why are ice algae one color and snow algae another? The two algal groups are unrelated, having diverged from a common ancestor 800 million to 1 billion years ago (Leliaert et al., 2012). Ice algae belong to the Streptophyta clade, which includes

Fig. 5 Greenland Ice-sheet glacier biota: (A) Ice algae, (B) Collembola, and (C) Snow algae.

many uni- and multicellular freshwater algae and land plants. Snow algae are members of the Chlorophyta clade, including diverse marine, freshwater, and terrestrial uni- and multicellular algae. Just as these two taxa independently evolved multicellularity, they similarly arrived at pigment-based solutions to living on ice. The common ice-alga genera (*Mesotaenium*, *Ancylonema* and *Cylindrocapsa*; Kohshima et al., 1993) generally use a phenolic pigment, purpurogallin, to absorb abundant radiation and gives their icy habitat a purplish tint. Common snow-alga genera (*Chlamydomonas*, *Chloromonas* and *Chlainomonas*); (Remias et al., 2016) use a secondary carotenoid, astaxanthin, for the same purpose, coloring the snow they inhabit with their unicellular bodies as red, pink, or even orange. Neither purpurogallin nor astaxanthin is involved in photosynthesis. Instead both pigments block light from photosynthesis, absorbing the wavelengths to generate heat.

Research (Dial et al., 2018) into the melting potential of a red particle reveals that it thaws almost as much as a purple particle, but does so with a lessened heat load on the particle itself; a red particle melts ice both by conduction of absorbed light, and by reflection of red wavelengths, preferentially absorbed by snow and ice. Astaxanthin itself is esterified in fatty deposits filling the cell interior (Bidigare et al., 1993), the likely source of watermelon snow's smell (esters give fruit its distinctive odor). Fatty astaxanthin may also keep an algal cell on the surface of the snow, as oil does on water. Otherwise it might sink into the snow like mineral particles do as they melt into the snow around them.

Glacier travelers often overheat when skiing in black. The same would occur with a black snow alga cell. Ice worms, on the other hand, are black through and through, including their organs. They stay out of the sun, emerge only at night, but likely absorb the purple and blue light that readily penetrates snow. Green is the coolest color in direct sunlight, absorbing the least energy. Dial et al. (2018) conjectures that chlorophyll is green to prevent terrestrial plants from overheating. Green-colored pigments reflect the most abundant wavelength of sunlight to keep cool, the inverse of glacier algae's needs.

Taxa Living on Glacier Ice and Snow

Studies (reviewed by Kaczmarek et al., 2016) of cryoconite holes report ammonia-oxidizing archaea, nitrogen-fixing bacteria, filamentous cyanobacteria (Oscillatoriaceae) which bind with mineral particles, ciliated protozoa, diatoms (Stanish et al., 2013), purple, red, and orange-colored green algae, as well as a variety of snow and ice fungi. Obligate-glacier dwelling animals include cryoconite copepods (Hexanauplia: Copepoda: *Glaciella yalensis* Kohshima, 1987; Kikuchi, 1994; Takeuchi et al., 2000) and flightless midges (Insecta: Diptera: Chironimidae: Diamesinae; Kohshima, 1984) on Himalayan glaciers; semi-flightless midges (Insecta: Diptera: Chironimidae: Podomoninae) on New Zealand glaciers (Odell, 1956; Dumbleton, 1973; Boothroyd and Cranston, 1999); two species of stoneflies (Insecta: Plecoptera: Gripopterygidae) in Patagonia (Kohshima, 1985; Vera et al., 2012; Murakami et al., 2018; Pessacq and Rivera-Pomar, 2019); springtails (Insecta: Collembola; Fjellberg, 2010) worldwide; glacier ice worms (Annelida: Oligochaeta: Enchytraeidae) in North America's Pacific northwest (Wright, 1887; Emery, 1898; Tynen, 1970; Goodman, 1971; Shain et al., 2001; Hartzell et al., 2005; Dial et al., 2012; Dial et al., 2016) and Tibet (Liang, 1979); nematodes in Antarctica (Mueller et al., 2001) and Europe (Azzoni et al., 2015); as well as nearly pan-glacial (Zawierucha et al., 2015) tardigrades (Desmet and Vadrompus, 1994; Zawierucha et al., 2016) and rotifers (Desmet and Vadrompus, 1994; Porazinska et al., 2004; Kaczmarek et al., 2014). Facultative-glacier dwelling organisms include moss and the animals associated with that habitat such as rotifers, tardigrades, mites, and collembola (Hotelling et al., 2019).

Algal Blooms

Because albedo reduction on glaciers and ice-sheets plays an important role in further warming of Earth's atmosphere (Skiles et al., 2018), substantial current research interest focusses on snow and ice-dwelling algae and cyanobacteria: their albedo-reducing properties (Lutz et al., 2016; Stibal et al., 2017; Perini et al., 2019), ecological limitations (Ganey et al., 2017; Hamilton and Havig, 2018), and detection using remote sensing—such as by drones (Ryan et al., 2018), aircraft (Painter et al., 2001), and satellites (Takeuchi et al., 2006; Ganey et al., 2017; Huovinen et al., 2018; Tedstone et al., 2019). Most remote sensing studies use ratios of reflectance bands of onboard camera-like sensors to indicate likely algal blooms. For example, Takeuchi et al. (2006); Ganey et al. (2017) found that the ratio of red-light to green-light intensity as seen reflected from Alaskan glaciers was well-correlated with snow algae abundance there. Tedstone et al. (2019), Ryan et al. (2018) have applied similar approaches to ice algae on GrIS and Huovinen et al. (2018) to snow algae in Antarctica. These remote sensing approaches require ground-based counts of algae with simultaneous spectroscopic reflectance sampling of various densities of algae-covered snow across the wavelengths of light measured by the airborne or satellite-borne sensors.

Two groups of algae from distantly related taxa—the ice algae in the Zygnematophyceae and snow algae in the Chlamydomonadaceae—reduce albedo on glaciers (Anesio and Laybourn-Parry, 2012). Snow algae have a complex life cycle that includes dormant cysts that overwinter, flagellated cells that disperse, and vegetative cells that photosynthesize on the snow surface (Hoham and Duval, 2001). Ice algae have a simple life cycle whereby cells prepare for winter by increasing fatty acid concentration, yet produce no special cells, nor are they motile. Glacier algae (Williamson et al., 2019) prefer to settle on mineral particles (Takeuchi, 2001; Remias et al., 2005; Stibal et al., 2017), perhaps because these provide nutrients, attachment substrates in an unstable habitat or as centers for consortia among microbes (Thomas and Duval, 1995; Remias et al., 2005; Perini et al., 2019).

If algal cells melt frozen surface water by absorbing abundant wavelengths of light, while benefitting from liquid water and nutrients liberated from ice and snow crystals, then algae will increase in abundance, further increasing melt in a positive feedback (Stibal et al., 2012; Benning et al., 2014; Ganey et al., 2017). This hypothesis was tested on an icefield in Alaska by Ganey et al. (2017). To determine if increased algal abundance, increased melt, the scientists applied Nitrogen–Phosphorous–Potassium (NPK) fertilizer to increase algal abundance while simultaneously measuring snowmelt. The experiment showed that addition of NPK increased algal abundance, that increased algal abundance increased melt, and that additional water increased algae, experimentally supporting the feedback hypothesis. Other nutrient studies suggest nitrogen addition from birds (Fujii et al., 2010), iron addition from volcanoes (Harrold et al., 2018), and even inorganic carbon addition (Hamilton and Havig, 2018) can increase snow alga abundance (Ren et al., 2019).

The Biogeography of Macroinvertebrates

Glacial macroinvertebrates are sparse as a group across the world's glacial biome (Table 1). Macroscopic metazoans that are glacially obligate (segmented worms and insects) occur primarily on warm glaciers with high precipitation, such as temperate west coast mountains and the Himalaya with wet summer monsoon. These are west-coast mountain ranges of New Zealand's South Island, North and South America, and the Greater Himalaya at the headwaters of the Ganges and Brahmaputra Rivers. While Scandinavia and Iceland also have west coast mountain ranges, their glaciated regions have been apparently either too small or, more likely, too cold to evolve psychrophilic macroinvertebrates. Based on Bayesian phylogenies of mitochondrial DNA, the North American glacier ice worm (*Mesenchytraeus solifugus*) evolved as three species-level clades (Dial et al., 2016, 2012) on the warm, wet coastal edge of a continental scale ice-sheet located at temperate latitudes. While certainly the most abundant and widespread of all glacial macroinvertebrates, with populations reaching the hundreds of millions or billions on Alaskan glaciers and icefields (Goodman 1971; Shain et al., 2001), the ice worm is sensitive to cold: temperature below about -7°C (25°F) are lethal (Edwards, 1985).

Table 1 Select glacier obligate taxa and their relative abundance distribution across the glacier biome.

Region	Latitude	Plecoptera	Annelida	Diptera	Collembola, Rotifers, Tardigrades	Snow algae	Ice algae
Himalaya	Subtropical		+	+	++	+	++
North America	Temperate		+++		+++	+++	+++
Patagonia	Temperate	+			+++	++	++
New Zealand	Temperate	+			+++	++	++
Europe	Temperate				+++	++	++
Greenland	Polar				++	+	+++
Antarctica	Polar				+	+	+

+: present; ++: abundant; +++: very abundant.

The Biogeography of Glacier Microbes

Like most taxa in most environments, the explosion of advances in technology and computation have revolutionized studies of microbial biogeography. Microbes found on glacier surfaces have been shown to be far more extensive in their distributions than metazoans, as expected from the microbial cosmopolitan dispersion hypothesis: “Everything is everywhere, but the environment selects” (De Wit and Bouvier, 2006). Most studies of the glacier microbiome support this hypothesis in that a few cosmopolitan species dominate glacier ecosystems, but endemism also exists (Segawa et al., 2018; Remias et al., 2018), particularly in gut symbionts of macroinvertebrates (Murakami et al., 2015, 2017, 2018). For example, red snow algae are reported to be not only cosmopolitan across the Arctic (Lutz et al., 2016), but to show DNA haplotypes found in both arctic and Antarctic environments (Segawa et al., 2018). Fungi are less well-known, but studies show that fungi are also a consistent component of algal blooms across the Arctic (Maccario et al., 2014) and Antarctic (Davey et al., 2019). While morphological species seem widespread among all microbial groups residing on glaciers, an observation consistent with genetic studies, unique sequences are present in each region as well. Future studies will reveal more about the complexities of microbial biogeography in the glacier biome.

Abstract

Natural freshwater ecosystems represent the terrestrial phases of the global hydrological cycle and include rivers, streams, lakes, ponds, wetlands as well as groundwaters. While fresh waters comprise only 0.01% of the water on Earth and constitute less than one-tenth of the global land surface area, they support >10% of all recorded species including ~30% of all vertebrates. Freshwater ecosystems support the provision of numerous ecosystem services which range from natural flood management, water supply, health, mental well-being to fish nurseries. However, freshwater ecosystems, their biodiversity and the services they provide are being jeopardized by a multitude of anthropogenic (human-mediated) stressors. Some of these threats are generated internally (habitat alteration, fragmentation, overexploitation) while others are external (invasive nonnative species, climate change, atmospheric pollution). Fortunately, many options for freshwater ecosystem conservation exist but require urgent action.

What Are Freshwater Ecosystems?

Natural freshwater ecosystems represent the terrestrial phases of the global hydrological cycle and include permanent rivers, streams, lakes, ponds, wetlands as well as groundwaters. Variations in precipitation, meltwater between seasons and hydrological events also lead to periodic or episodic inundation of floodplains, seasonal wetlands or temporary channels that form transient freshwater ecosystems to which many organisms are adapted. Artificial environments, such as canals, reservoirs, and drainage ditches, also support freshwater species. In contrast with marine and transitional ecosystems (e.g., mangroves, salt marshes, lagoons, estuaries, and open oceans), fresh waters are characterized by lower salt content (fresh water: <5 ppt vs. marine: >30 ppt) and are often subdivided into being “lotic” (flowing) or “lentic” (still) systems (Wetzel, 2001). Fresh waters occur around the world from the poles (e.g., glaciers, ice sheets) through temperate zones to the tropics. Yet, fresh waters comprise only 0.01% of the water on Earth and constitute less than one-tenth of the global land surface area (Lehner and Döll, 2004) while marine systems cover more than 70% of the globe and account for >97% of the Earth’s water (NOAA, 2018). Freshwater drainage basins (i.e., watersheds (North America; used hereafter) or catchments (United Kingdom)) are clearly defined units in terrestrial landscapes, formed where precipitation collects and drains downslope to a common outlet at lower elevation such as an estuary, bay or landlocked wetland (Fig. 1). Being both hydrologically connected and topographically low in the landscape means that fresh waters are open systems that transfer matter, energy and solutes, including pollutants, to and from neighboring ecosystems (Hynes 1975; Brooks et al., 2003). Their connected nature means they are conduits for the longitudinal or lateral movement of organisms, including invasive species, that are now among a wide range of stressors that endanger the disproportionately large biodiversity that inhabit these ecosystems (Reid et al., 2018).

Rivers and Streams

Rivers and streams are lotic systems that connect aquatic and terrestrial environments, circulating precipitation and sediments from the land to lakes, estuaries and oceans. They cover less than 1% of Earth’s nonglaciated land surface (694,000–852,000 km²; Allen and

Fig. 1 Major continental divides of the world, showing drainage of fresh waters into the major oceans and seas—gray areas are endorheic (terminal) basins that do not drain into marine ecosystems. Courtesy Public Domain.

Pavelsky, 2018). The world contains a diversity of rivers and streams—distinguished by permanency (e.g., permanent and intermittent), channel shape (e.g., braided and meandering), biodiversity (e.g., algae, invertebrates, fishes), ionic composition (e.g., major ions and macro-nutrients) and other factors—but the vast majority of riverine ecosystems have been altered by humans (Grill et al., 2019).

Lakes and Ponds

Lakes and ponds are lentic systems, many of which are fed and drained by rivers and streams. The world contains at least 304 million natural lakes spanning 4.2 million km² (Downing et al., 2006). However, the majority are small (>91% are 0.001–0.01 km² [0.1–1 ha]) and few are large (0.005% >100 km² [10,000 ha]; Cael and Seekell, 2016). Natural lakes and ponds are found predominantly in mountainous regions, rift zones and areas with ongoing glaciation. Many artificial lakes and reservoirs are constructed for agricultural or industrial purposes (e.g., hydroelectricity; Grill et al., 2019).

Freshwater Wetlands

Wetlands (e.g., swamps, marshes, bogs, and fens), which are either permanently or seasonally inundated by water, are among the most productive habitat types in the world. They cover an estimated 5.4–6.8% of the Earth's land surface area (Lehner and Döll, 2004). Wetlands are found on every continent and can be characterized as being saltwater, brackish (intermediate salinity) or freshwater. Artificial wetlands are also built for wastewater treatment and stormwater runoff.

The Immense Biodiversity of Fresh Waters

To many, freshwater biodiversity means “fish.” Yet, freshwater fish are but one of many organisms that live in fresh waters or depend upon freshwater ecosystems for nourishment or reproduction. While fresh waters comprise just a fraction of the water on Earth, they support >10% of all recorded species (Dijkstra et al., 2014; Mittermeier et al., 2010), estimated at ~126,000 freshwater-dependent species (IUCN, 2019). In fact, ~30% of all vertebrates live in freshwater ecosystems or are entirely dependent upon them—from the amphibians (which exceed 4300 species) and freshwater snakes and turtles to many aquatic birds and even some freshwater-dependent mammals (such as platypus and freshwater dolphins). If one considers just fish, the numbers are also impressive. Of the nearly 30,000 fish species identified to date, well over 10,000 of them are considered to be freshwater—with estimates of around 45% of all fish residing in freshwater at some point during their lives. Beyond the vertebrates, freshwater is also home to many plants and invertebrates. For example, according to the International Union for Conservation of Nature (IUCN, 2019), 5600 Odonata (dragonflies and damselflies), and 5000 mollusk species depend on freshwater habitats (Strong et al., 2007). Even freshwater crabs are incredibly abundant with nearly 1500 species (Yeo et al., 2007). Fresh water clearly has disproportionately high biodiversity. Freshwater wetlands as well as rivers and littoral zones of lentic systems are also home to many plant and algae species albeit they have not been well inventoried from a biodiversity perspective (Denny, 1994; Spence, 1982).

Freshwater Ecosystem Services

Freshwater ecosystems support the provision of numerous ecosystem services—the diverse benefits, both material and nonmaterial, that people obtain from ecosystems (MEA, 2005). Another way to think of ecosystem services is as the contributions nature makes to people (Díaz et al., 2018). Examples of the benefits people derive from freshwater ecosystems vary from having clean water to drink, to feeling a spiritual connection to rivers, lakes and wetlands, to avoiding flooding events and the associated consequences. Freshwater systems also support numerous important ecosystem processes, such as nutrient cycling, which are sometimes referred to as “supporting services” (Carpenter et al., 2009).

The concept of ecosystem services is useful to help freshwater researchers and practitioners consider the diverse ways these systems interact with, and contribute to, human well-being. It encourages a holistic approach to thinking about ecosystems in terms of both social and ecological dimensions (MEA, 2005), with numerous interacting components that vary across space and time (Rodríguez et al., 2006). An associated challenge with employing the ecosystem services concept, however, is how to accurately assess and quantify services. Although there is no single standard method that can be broadly applied to assess freshwater ecosystem services, and ultimately, the appropriate method depends on the purpose of assessment, there are fortunately a growing number of ways this is being achieved in freshwater ecosystems (Table 1) and robust recommendations for how to conduct holistic assessments considering freshwater specific features such as connectivity (Hanna et al., 2018).

Freshwater Biodiversity in Crisis

Despite the importance of fresh waters and their flora and fauna to human needs and wellbeing, freshwater biodiversity is in crisis (Harrison et al., 2018). Global estimates show that freshwater species populations have declined on average by 83% over the last

Table 1 Examples of freshwater ecosystem services and methods that can be used to assess them.

<i>Selected freshwater ecosystem services</i>	<i>Example methods that can be used to quantify freshwater ecosystem services</i>
Drinking water	Water samples collected from a water source used for drinking and analyzed for nutrient concentrations, bacteria, and trace-metals to assess the quality of water for drinking A web-based survey sent to residents of a watershed asking them where they source their drinking water and how satisfied they are the quality and quantity of water they have access to
Sense of place	Interviews with people living within X kilometers of a stream asking them to describe if and how that stream contributes to their sense of place Interviews with people living within X kilometers of a stream asking them what monetary value they would be willing to pay to maintain their access to that stream
Recreation (e.g., paddling)	Distribution of a survey to park visitors determining if recreational paddling was one of the activities they conducted during their visit Classification of rapids along a river in terms of their recreational value for recreational white-water paddling
Food provision (e.g., fish)	Participatory mapping assessing locations visited by relevant community members to catch fish and the amount and species of fish caught Assessment of locally relevant fish contaminant concentrations (e.g., mercury, chromium) to assess the quality of fish for consumption
Flood mitigation	The percent of wetland coverage in a watershed, used as a proxy for the relative capacity for flood mitigation The amount of people found in a floodplain and the financial values of their assets as a means to assess the importance of flood mitigation

Before assessing freshwater ecosystem services researcher or practitioners have to make decisions concerning which ecosystem services are relevant for quantification, the appropriate spatial and temporal scales of assessments, the aspect of ecosystem services that is of interest—that is, do they want to quantify the capacity of a system to provide a service, the actual provision of a service, or the demand for a service, the best indicators that can be used to represent the services they are trying to quantify and establish who are the appropriate stakeholders or individuals that should be involved with quantification.

four decades (Fig. 2; WWF, 2018). Knowledge of the conservation status and distribution of freshwater taxa is limited relative to terrestrial species (Darwall et al., 2011), yet there is growing evidence that extinction risk in fresh waters is exceptionally high. Currently, almost one in three freshwater species is threatened with extinction worldwide, exceeding the risk of extinction compared to their terrestrial counterparts (Collen et al., 2014). Reptiles are potentially the most threatened freshwater taxa, with nearly half of species threatened or near threatened (Collen et al., 2014). Moreover, 40% of assessed freshwater bivalves (Lopes-Lima et al., 2018), 32% of all crayfish (Richman et al., 2015), 32% of all amphibian species (Stuart et al., 2004), 32% of assessed crab species (Cumberlidge et al., 2009), 25% of all mammals and fish (Collen et al., 2014), and 10% of assessed dragonflies and damselflies (Clausnitzer et al., 2009) are near threatened, threatened or extinct, according to the IUCN Red List criteria. This lends urgency to the study of diversity and of the relative risk of extinction of species in freshwater ecosystems, yet freshwater species remain a low priority on national and international conservation agendas, such as the United Nations Sustainable Development Goals (SDGs; Lynch et al., 2017; Reid et al., 2017). Conservation of freshwater biodiversity is partly impeded by an inadequate understanding of the economic value of freshwater species (and the services they provide) as well as a robust understanding of how freshwater species are at risk from multiple interacting stresses.

Fig. 2 The World Wide Fund for Nature (WWF) Living Planet Index (LPI) reveals remarkable decreases for freshwater species relative to marine or terrestrial species. These index declines are relative to a benchmark value of 100 in 1970. Dates given here refer to years in which estimates of abundance were made, as LPI reports typically refer to data from 4 years earlier (e.g., the 2016 LPI is based on 2012 data). Data from World Wildlife Foundation (WWF). (2018). Living Planet Report—2018: Aiming higher. In: Gland, Grooten, M. and Almond, R. E. A. (eds.). WWF.

Anthropogenic Stressors

Despite this downward trajectory for freshwater taxa, less than 20% of recent papers deal with aquatic species demonstrating a persistent bias in the conservation literature towards terrestrial organisms (Di Marco et al., 2017). This is problematic for many reasons. Firstly, terrestrial biodiversity indicators are a poor surrogate for freshwater biodiversity (Darwall et al., 2011). Furthermore, while some leading freshwater conservation solutions depend on management at the terrestrial/freshwater interface (e.g., reduced agricultural runoff), many land-based conservation efforts for freshwater biodiversity require implementation over large spatial extents at channel, riparian (relating to river banks) or watershed scales (Darwall et al., 2011). Finally, and as demonstrated above, freshwater ecosystems represent hotspots of endangerment due to the convergence of biological richness and the many forms of human freshwater exploitation. Due to an incurred 'debt' arising from low-viability populations that are in the process of dwindling to extinction, it is likely that freshwater extinction risks will remain high over the forthcoming decades (Strayer and Dudgeon, 2010). Nor will anthropogenic pressures on freshwater ecosystems ease soon, in view of the threats reviewed below.

Why are freshwater species facing such high rates of extirpation and extinction? The answer, in part, was outlined in a seminal review paper by Dudgeon et al. (2006), "Freshwater biodiversity: importance, threats, status and conservation challenges." Here, they identified (i) overexploitation, (ii) water pollution, (iii) flow modification, (iv) destruction or degradation of habitat, and (v) invasion by exotic species as the five leading causes of population declines and range reductions of freshwater organisms worldwide. This authoritative paper has been cited over 1800 times, placing it among the top-cited 1% of papers in the field of Biology and Biochemistry (Web of Science®). However, over the last decade, and as we advance into the epoch now being referred to as "The Anthropocene" (Crutzen, 2006), these threats have escalated and/or evolved, and new or previously unrecognized threats have become more apparent. To address this knowledge gap, Reid et al. (2018) provided a critical update on the status and threats to global freshwater biodiversity. Therein, they identified (i) changing climates, (ii) e-commerce and invasions, (iii) infectious diseases, (iv) harmful algal blooms, (v) expanding hydropower, (vi) emerging contaminants, (vii) engineered nanomaterials, (viii) microplastic pollution, (ix) light and noise, (x) freshwater salinization, (xi) declining calcium, and (xii) cumulative stressors as the most significant contemporary challenges to freshwater conservation (Fig. 3; Table 2; see Reid et al., 2018 for references).

Options for Freshwater Ecosystem Conservation

Protect the best, restore the rest, adapt where pressed.

As revealed throughout this review, pressures and threats to the world's freshwater ecosystems arise at all scales from the local to the global. They are propagated through the aquatic, groundwater, riparian and watershed systems from which lake, rivers and wetlands are formed. Some of these threats are generated internally (habitat alteration, decreased longitudinal or lateral connectivity, pollution, over-exploitation) while others are external (invasive nonnative species, climate change, atmospheric pollution; WWF, 2018). Additional complexity also arises as threats to freshwater ecosystems evolve (Reid et al., 2018). Some of the resulting changes affect freshwater species directly, while alteration in fluxes or exchanges of nutrients, matter and energy affect many ecosystem processes with indirect consequences for populations, species or communities of organisms (Table 2).

Approaches to freshwater ecosystem conservation should ideally be effective in the face of all of these threats and pressures, while also protecting as completely as possible the Earth's diversity of freshwater organisms, freshwater ecosystems and the services they provide. Set against this ideal, however, is the fact that freshwater ecosystems are embedded in terrestrial landscapes whose use and management is seldom focused on conservation, but more on activities such as agriculture, silviculture, extractive industries, urban land or transport that can each cause downstream change or lead to the direct exploitation of water and associated resources. In many freshwater ecosystems, the consequences have developed over decades to centuries—meaning that conservation often has to involve repair or restoration of areas degraded by past impacts as well as the protection of more natural ecosystems.

Boon (1992a,b) developed a hierarchy of options for conserving freshwater ecosystems which ranged from "protection" where systems were relatively pristine; "limitation" or "mitigation" of damage where economic activities were sanctioned in or around freshwater ecosystems; through to "restoration" where past impacts would be reversed. A further option has since been recognized where impacts are considered inevitable—for example from climate change—and involves "adapting" freshwater ecosystems to accommodate or offset the worst effects (Thomas et al., 2016). Hierarchical concepts like these have been the source of the conservation mantra: "protect the best, restore the rest, adapt where pressed."

No matter where in this hierarchy conservation options are applied to freshwater ecosystems, there are two major and related constraints. The first stems from the connections between freshwater ecosystems and their surroundings through which fluxes and flow-paths bring both positive (e.g., resource subsidies) and negative effects (e.g., pollutants; Hynes, 1975; Likens, 2013). The ideal conservation strategy would be to designate, protect, manage or restore entire watersheds as reserves to control such fluxes, but competition with other land-uses often forces compromises so that action can only be localized (Fig. 4). The second major issue is one of scale: where freshwater ecosystems are large—such as in the case of the World's great lakes or river systems—the sheer spatial extent over which conservation problems arise is a challenge in its own right, for example because drainage basins are extensive (often international), while organisms adapted to these systems have endemic character or migratory life cycles that require protection ideally over entire systems such as from source to sea.

Fig. 3 The five major threat categories and their established or potential interactive impacts on freshwater biodiversity from Dudgeon et al. (2006), shown in the inner gray circles. The 12 major threat categories and their established or potential interactive impacts on freshwater biodiversity from Reid et al. (2018), shown in the outer yellow circles.

In non-aquatic ecosystems, the designation of nature reserves is a mainstay of conservation action, and this same approach has been applied to freshwater ecosystems for decades—for example through the specifically aquatic Ramsar Convention (Gardner et al., 2015), through European Natura 2000 Sites under the European Union Habitats Directive (92/43/EEC), or in the United Kingdom as Sites of Special Scientific Interest. In most of these cases, however, designated areas achieve only limited reach, for example from bank-to-bank in rivers, occasionally extending into riparian zones or floodplain wetlands, or to the protection of headwaters often as part of larger terrestrial reserves. In the absence of the protection of freshwater ecosystems at scale, alternative approaches attempt to control or regulate some adverse pressures—a prime example being Europe’s Water Framework Directive (WFD 2000/60/EEC). The WFD simultaneously identifies adverse pressures while encouraging beneficial “programs of measures” to protect or restore freshwaters to “good ecological status”—for example through reduced nutrient inputs or improved wastewater treatment.

Beyond designation or restoration, other potential instruments to encourage freshwater conservation include government financial incentives to replace “income foregone”—for example as part of agri-environment schemes where land-owners are funded to provide sensitive land-management in place of intensification. Voluntary “codes of practice,” for example in the production forestry, extractive or building industries, also set standards by reducing damaging practice. Large-scale demonstration activities sometimes illustrate how freshwaters can be protected in freshwater ecosystems where Indigenous peoples, governments or nongovernmental organizations can influence land management at scale. Increasingly, also, market mechanisms are being explored to protect or restore freshwater through “natural capital” or “markets for ecosystem services” that account more fully for the benefits provided by high quality freshwater ecosystems—for example reduced treatment costs in water supply, natural flood management, health and mental being, or nurseries for important fish stocks (Ormerod, 2014). Key needs in applying such market mechanisms are in identifying providers and users of ecosystem services, ensuring that payments and benefits flow accordingly, and in sourcing investments to fund schemes equitably and sustainably.

Table 2 Characteristics of long-standing (indicated by 'a' superscript) and emerging ('b' superscript) threats to freshwater biodiversity: their geographical extent (and focal regions); the severity of their effects; examples of attendant ecological changes; our degree of understanding; and potential options for mitigating threat effects.

<i>Emerging threat (regions)</i>	<i>Severity of effects</i>	<i>Ecological changes</i>	<i>Degree of understanding</i>	<i>Mitigation options</i>
Over-exploitation (global) ^a	Already causing extinctions; likely to cause more	Alters species size, range, and survival (target + bycatch)	Well understood, but interactive stressor effects unclear	Global commitments; expand freshwater protected areas
Water pollution (global) ^a	Already causing extinctions; likely to cause more	Alters species survival, with clear ecosystem effects	Increasingly well understood but high unpredictability	Improve surveillance; management to favor ecosystem controls
Habitat degradation (global) ^a	Already causing extinctions; likely to cause more	Alters species survival, with clear ecosystem effects	Well understood, but interactive stressor effects unclear	Global commitments; expand freshwater protected areas
Species invasion (global) ^a	Already causing extinctions; likely to cause more	Alters species survival, with clear ecosystem effects	Increasingly well understood but high unpredictability	Improve surveillance; management to favor ecosystem controls
Flow modification (global) ^a	Already causing extinctions; likely to cause more	Fragments river systems, inhibiting species movement	Well understood, but interactive stressor effects unclear	Ameliorate passage infrastructure; assess all project impacts
Changing climates (global) ^b	Already causing extinctions; likely to cause more	Alters species size, range, phenology, and survival	Moderately well understood but high unpredictability	Global commitments; expand protected areas; restore refugia
E-commerce and invasions (global) ^b	Significant role in trade of nonnative plants and animals	Creates novel modes of long-distance dispersal	Largely unregulated activities that are poorly understood	Online consumer accountability tools; awareness campaigns
Infectious diseases (tropics) ^b	Already causing extinctions; likely to cause more	Alters species survival, with clear ecosystem effects	Increasingly well understood but high unpredictability	Improve surveillance; management to favor ecosystem controls
Harmful algal blooms (nutrient-rich, warm) ^b	Linked to species losses; likely to cause more	Reduces species growth, survival, and reproduction	Increasingly well understood, some unpredictability	Improve surveillance; management to favor ecosystem controls
Hydropower (emerging markets) ^b	Already causing extinctions; likely to cause more	Fragments river systems, inhibiting species movement	Well understood, but interactive stressor effects unclear	Ameliorate passage infrastructure; assess all project impacts
Contaminants (developed markets) ^b	Unclear how biodiversity will be changed	Alters some species health, abundance and reproduction	Largely understudied and thus poorly understood	Improve medication disposal; advance wastewater treatment
Nanomaterials (developed markets) ^b	Unclear how biodiversity will be changed	Causes minimal acute toxicity in some species	Considerable uncertainty around long-term effects	Improve detection and characterization; create targeted formulations
Microplastics (developed markets) ^b	Unclear how biodiversity will be changed	Potentially detrimental effects on species health	Considerable uncertainty around long-term effects	Reduce plastic usage; legislation to curb use of specific products
Light and noise (developed markets) ^b	Linked to species disturbance; likely to continue	Alters behavior and physiology of some species	Well understood, but ecosystem-level effects unclear	Identify less harmful types; reduce usage; educate users
Salinization (coastal lowlands) ^b	Linked to species losses; likely to cause more	Reduces species growth, survival, and reproduction	Increasingly well studied and understood	Control point sources; strategic release of freshening flow
Declining calcium (softwater lakes) ^b	Linked to species declines; likely affecting foodwebs	Causes shifts in lake invertebrate assemblages	Increasingly well understood; solutions unevaluated	Further reduce acidic precipitation; replenish calcium in watersheds
Cumulative stressors (global) ^b	Contributing to extinctions; likely to cause more	Magnifies impacts; create ecological surprises	Poorly understood with high levels of unpredictability	Identify multipurpose solutions that protect biodiversity hotspots

Socio-Political Dimensions of Freshwater Conservation

Fresh water is distributed across the terrestrial landscape as river, lake, and wetland systems, typically arranged as watersheds whereby water flows from upland areas to lowland areas (Figs. 1 and 3). Watersheds have long been recognized as logical planning and management units given that they inherently link land and water (Hynes, 1975) and transcend geopolitical boundaries. This has been amplified in recent years given that watersheds are an example of a coupled social-ecological system and should be managed accordingly (Nguyen et al., 2016). For centuries humans have settled on or near freshwaters for transportation, irrigation,

Fig. 4 Options for the conservation of key features affecting freshwater ecosystems. Schematics of freshwater protected area zones include: (A) freshwater focal areas (e.g., particular river reaches, lakes, headwater streams, or wetlands supporting focal species, populations, or communities); (B) critical management zones, such as river reaches connecting key habitats or upstream riparian areas; and (C) a catchment management zone, covering the entire catchment upstream of the most downstream freshwater focal area or critical management zone. Modified from Abell, R., Allan, J. D. and Lehner, B. (2007). Unlocking the potential of protected areas for freshwaters. *Biological Conservation* **134**, 48–63.

power (initially for mills and now for electricity), drinking water, and food (fish) yet humans have also altered the lands that drain and contribute flow to freshwater systems. Given human dependence on contemporary land-use change (e.g., roads, dams, agriculture, forestry, and urbanization), conservation of freshwater biodiversity is remarkably challenging (Crist et al., 2017). Indeed, it is generally understood that the most profitable path toward the conservation of freshwater biodiversity requires engaging with sectors that use water or otherwise alter upland areas that indirectly contribute to biodiversity loss via habitat alteration (e.g., water quality impairments, loss of spawning habitats) as demonstrated above. In the marine realm, one of the biggest drivers of biodiversity loss is overfishing which can most easily be solved by working directly with resource users rather than in freshwater where the industries and actors that negatively influence freshwater biodiversity (e.g., farmers) may be very disconnected and lack the incentives to do so (Beard et al., 2011).

Freshwater biodiversity loss is often considered to be a hidden crisis in that much freshwater biodiversity is unobserved beneath the water surface (Reid et al., 2018). As such, it has been difficult to generate the public and political will to enable meaningful investments or behavioral change needed to protect and restore freshwater biodiversity (Cooke et al., 2013). Grassroots, community-driven actions and stewardship are often heralded as the path forward for freshwater conservation (Silk and Ciruna, 2013) yet that alone fails to account for the broad-scale threats facing such systems. The so-called “food-energy-water nexus” (Smajgl et al., 2016) emphasizes the inherent interconnections of these major issues. Should we prioritize biodiversity preservation over stable energy sources or food for people in some of the most impoverished regions of the globe? Clearly there are difficult ethical, socio-economic and political discussions needed to chart a responsible path forward that represents a win-win-win scenario where freshwater biodiversity is both valued and protected. Global policy instruments often fail to consider freshwater biodiversity (summarized in Darwall et al., 2018) as it is considered a “domestic issue” yet there is a need for elevating freshwater biodiversity to one that is of common global concern (Harrison et al., 2018). Working from both bottom-up and top-down is essential for valuing freshwater biodiversity and committing to a future where we not only respect and conserve freshwater biodiversity but work to actively restore it.

Abstract

Temporary wetlands are characterized by frequent drying resulting in a unique, highly specialized assemblage of often rare or specialized plant and animal species. They are found on all continents and in a variety of landscape settings. Although accurate estimates of the abundance of temporary wetlands are available in only a few countries, global estimations identify a decline in number and quality. The key environmental factors driving the structure of ecological communities in temporary wetlands are the duration, timing, frequency and predictability of the aquatic and dry phases, which varies greatly with region and hydrogeomorphic setting. Temporary wetlands have been historically neglected, but improved social awareness of the functions and values of, and increases in scientific interest, suggest that this is changing. They play an ecological role in both global cycles (i.e., CO₂ emissions) and biodiversity (in proportion to their size, they contribute disproportionately to regional and global biodiversity). Moreover, they provide valuable ecosystem services including wildlife habitat, nutrient flux to adjacent ecosystems, flood control, water filtration, and cultural services. Effective conservation of temporary wetlands requires addressing threats (i.e., inconsistent and inadequate regulatory protections; climate change; changes in land use) and management challenges (i.e., management at both local and landscape scales; incomplete understanding of the ecosystem services provided by them; the need to enhance inventories). The most suitable approaches for conserving temporary wetlands include (1) regulations or other forms of protection; (2) sustainable management; (3) restoration and creation; and (4) collaborative conservation.

What Are Temporary Wetlands?

Temporary wetlands are wetlands characterized by frequent drying (normally they dry completely, at least, once a year) resulting in a unique, highly specialized assemblage of often rare plant and animal species (Calhoun et al., 2017). Their defining feature is hydroregime (duration, timing, frequency and predictability of the aquatic phase; Vanschoenwinkel et al., 2009; Sim et al., 2013), and, in some regions, the cyclical nature of droughts, as some permanent water bodies may dry in exceptional

years (Williams, 2006). While throughout our discussion we refer to these landscape features as “temporary wetlands,” it is only the ponded water in the wetland that is temporary in nature. The wetlands themselves are persistent features of a landscape that exist unless drained or filled (Van der Kamp et al., 2016). Usually the water turnover rate is considered the primary environmental cue used to identify the different types of freshwater ecosystems (Margalef, 1983; Wetzel, 2001). Thus, wetlands with short turnover periods (i.e., lotic environments; streams and rivers) differ in both function and community structure than those with longer turnover periods (i.e., lentic environments; wetlands). Hydroregime is the main environmental indicator of gradients in lentic environments (Schneider and Frost, 1996; Wellborn et al., 1996). Hydroregime not only implies physical and biogeochemical changes (especially carbon cycling) in the habitat, but also drives ecological interactions by shaping food webs and altering the composition of potential competitors and predators of species previously adapted to temporary water regimes (Williams, 2006; Lake, 2011).

Where Are Temporary Wetlands Found?

Temporary wetlands are found on all continents, even in Antarctica (Antarctic melt-water ponds), and in a variety of landscape settings, although temporary wetlands exhibit regional differences because different typologies are especially abundant in some areas (Fig. 1) (Zedler, 2003; Williams, 2006; Calhoun et al., 2017). Temporary wetlands are important features in landscapes where permanent water sources are rare (i.e., semiarid and arid areas; Williams, 1985). Many of these wetland features were recognized by ancient cultures and are still considered a valuable part of regional heritage. For example, Aristotle described the biological functioning of one Mediterranean temporary wetland in his “History of Animals” (Boix et al., 2016); Australian Aboriginal people shared knowledge passed down from generation to generation with Europeans about the temporary “gnamma” holes, which were one of their main sources of water (they even elaborated a technique to deepen them) (Bayly, 1999). In addition, temporary wetlands have been created in Europe by humans at least since Roman and Gallo-Roman times as agricultural ponds (Derex, 2001; Delhoofs et al., 2010). Deliberate wetland creation (for runoff and flooding abatement or as incidental features from forestry or development practices) are still common today (Calhoun et al., 2014a).

Estimates of the location, surface area, abundance, and relative importance of temporary wetlands are available in only a few countries and often only for some regions. However, a global estimation shows that in a contemporary timeframe (i.e., 2015), seasonal water covered 0.81 million km², and in the last three decades the transition from permanent to seasonal waters was higher than the reverse transition (72,000 km² and 29,000 km², respectively) (Pekel et al., 2016). In some areas, shifts to more permanent water regimes have occurred, either through the drainage of many smaller wetlands into fewer larger wetlands, which is known as “consolidation drainage” (McCauley et al., 2015); through the construction of dugouts or dikes in wetland basins (Euliss and Mushet, 2004); or through increases in timing and intensity of rainfall events as a result of changing climate regimes (McKenna et al., 2017).

Because they are temporary and generally small, temporary wetlands can be challenging to identify using remote-sensing techniques. Advances in technology, including light detection and ranging (LiDAR), can improve global inventories of temporary wetlands (e.g., Gómez-Rodríguez et al., 2010; Rhazi et al., 2012; Tulbure et al., 2014; Wu et al., 2014). This knowledge is crucial for evaluating their number, distribution, and perhaps increasing their value to society (small waterbodies have been poorly inventoried and undervalued; Downing et al., 2006); and to track widely reported losses (e.g., Brown, 1998; Euliss and Mushet, 1999; Rhazi et al., 2012). Although auditing the numbers and size of wetlands remains a challenge (Jeffries et al., 2016), global estimations identify a negative trend. Since the beginning of the 18th century, wetland loss (mainly inland, temporary wetlands) could have been greater than 80% and wetland loss in the 20th century was almost four times faster (Davidson, 2014). For this reason, the functions and values of temporary wetlands need to be acknowledged and better understood.

Diversity of Temporary Wetland Physical Attributes

Most lentic temporary environments can be considered temporary wetlands, with the exception of some unique habitats (e.g., phytotelmata, a small water-filled cavity in a terrestrial plant). Temporary wetlands are globally distributed and shaped by distinct climate conditions in a variety of biomes and thus encompass a wide range of attributes (Williams, 1985; Williams et al., 2010). For example, although temporary wetlands are generally shallow and relatively small, they vary in (1) size (from a few square centimeters of some rock-pools to hundreds of square kilometers of North American “playas” or thousands of square kilometers of ephemeral Australian lakes), (2) substrate (rock, sand, clay), (3) hydroregime (from ephemeral water bodies in arid regions to seasonal ponds in temperate zones), and (4) sources of water input (rain, snowmelt, stream flow, subterranean). Thus, although rain provides the main water input to temporary wetlands in a great number of regions, in others snowmelt or subterranean waters can play this role (e.g., Irish “turloughs”) and be a determinant of long-term changes in wetland permanence (LaBaugh et al., 2018). Therefore, temporary wetlands comprise a wide range of worldwide waterbody types (Fig. 1), resulting in diverse names to describe them (Williams, 2006; Williams et al., 2010; Calhoun et al., 2017).

Isselin-Nondedeu); Mediterranean temporary pond, Albera piedmont, Catalonia, Spain (photo: A. Ruhi); dry vernal pool, Acadia National Park, Maine, United States (photo: A. Calhoun); Great Plains prairie pothole, North Dakota, United States (photo: D. Mushet).

Key Environmental Variables and Classification of Temporary Wetlands

The key environmental factor driving the structure of ecological communities in temporary wetlands is hydroregime. Hydroperiod length or pond duration is the most studied hydrologic component, in large part due to its influence over community dynamics and structure (Sim et al., 2013; Boix and Batzer, 2016). However, other aspects of hydroperiod also play a key role, such as predictability (Comín and Williams, 1994) or inundation timing (Kneitel, 2014). Interactions between hydroregime and various biological factors (i.e., predation pressure, strategies to resist desiccation or to recolonize rapidly) have been

documented (Wellborn et al., 1996; Jeffries et al., 2016). These interactions can be complex and difficult to predict, complicating identification of general patterns of how organisms will respond to hydroregimes (Batzler, 2013), a fact that contributes to the diversity of temporary wetlands.

Pond size is also considered a determinant factor for many features of temporary wetlands although this varies by region (e.g., Ebert and Balko, 1987; March and Bass, 1995; Meintjes, 1996; Spencer et al., 1999). Overall, indirect effects of pond size on community structure (i.e., larger ponds have different environmental characteristics than smaller ponds) seems to be weak in temporary ponds (Ballón et al., 2016). However, in forests, pond size may be correlated with tree canopy closure in some regions, which influences quantity of photosynthetic active radiation and inputs of organic matter consequently structuring part of ecosystem functioning (Mokany et al., 2008; Skelly et al., 2014). Moreover, the interaction of both factors, hydroregime and pool size, has been related to some ecological traits such as the dispersion of the taxa (Vanschoenwinkel et al., 2009).

Several methods for classifying temporary wetlands have been attempted including classification by the biome in which they are present (e.g., tundra, temperate grassland, Mediterranean scrub, tropical savanna), size (i.e., micro-, meso-, macro-habitats), hydrological character (i.e., intermittent, episodic), salinity (i.e., freshwater, saline), origin (natural, artificial; and the latter can be classified according to human use), indicator species, or a combination of several of these factors (Williams, 1985, 2006; Rheinhardt et al., 2008). Classifications based on hydrology, including duration and predictability of the hydroperiod, are frequently used (Comín and Williams 1994; Keeley and Zedler 1998). This includes the most widely accepted classification of temporary wetlands, proposed by Boulton and Brock (1999), which has been adapted and reproduced in several ecology textbooks (e.g., Boulton et al. 2014; Grillas et al., 2004; Williams, 2006; Boix et al., 2016). The classification distinguishes five types of temporary lentic waters (Table 1). These temporary wetlands types are related by potential future changes of hydroregime. Thus, trends of precipitation variation (increases or decreases, which are regionally dependent) and increase of extreme events (such as heavy precipitation events or long dry periods) predicted in accordance with climate change (Brooks 2009; Stocker et al., 2013) imply possible transitions among the separate types of temporary wetlands (Fig. 2).

The relevance of hydrology in shaping ecological function of temporary wetlands is also the core of the conceptual framework of the "Wetland Continuum" (Euliss et al., 2004). This conceptual framework is more comprehensive than the scenarios illustrated in Fig. 2 because it includes not only precipitation but also groundwater recharge or discharge, facilitating the interpretation of biological studies of wetland ecosystems (Mushet et al., 2018). The objective of the Wetland Continuum framework is "to provide

Table 1 Classification of temporary wetlands (TW) according to their hydroregime with some comments of the characteristics of the organisms living in them.

TW type	Flooding regime	Hydroregime	Organisms
<i>Ephemeral</i>		Filled only after unpredictable rain and by run-off. The flooded area dries out during the days following the flooding	Supports low numbers of macroscopic aquatic species compared to pools with longer hydroperiods
<i>Episodic</i>		Dries in 9 out of 10 years, with rare and irregular flooding (or wet periods) which may last for a few months	Terrestrial flora with few aquatic species. Fauna characteristic of temporary waters, dominated by species with highest dispersion capacity or drought resistant strategies
<i>Intermittent</i>		Alternating wet and dry periods, but a more irregular frequency of filling than seasonal wetlands. Flooding may persist for months or years	Aquatic flora restricted to the inner belt. Fauna characteristic of temporary waters, but also species that use waterbody as breeding or feeding site
<i>Seasonal</i>		Alternating wet and dry periods annually, in accordance with the season. Usually fill during the wet season of the year, and dry out in a predictable way every year	Since flooding lasts for several months, macroscopic animals and plants are able to complete their life cycles
<i>Near-permanent</i>		Predictable flooding, though water levels may vary. The annual input of water is greater than the losses (does not dry out) in 9 out of 10 years	The majority of organisms living here cannot tolerate desiccation

Fig. 2 Changes among temporary wetland types (according their hydroregime, see Table 1) in some future climate scenarios (Stocker et al., 2013) taking into account two aspects: variation in precipitation and increase of extreme events (i.e., heavy precipitation events or long dry periods).

a method that can be used to complement existing classification systems by placing dynamic shifts in wetland class and function within an ecological context to improve interpretation among biological studies conducted in different locales and times." This method is also a powerful tool for analyzing future changes in ecological functioning due to periods of wet or dry conditions (Mushet et al., 2018). Exemplary situations to which the Wetland Continuum framework may be applied include the Prairie Pothole Region of North America, which has been subjected to an extended period of extreme wet conditions (McKenna et al., 2017); or the substantial decline of annual rainfall observed since 1900 in several Mediterranean regions owing to climate change (IPCC, 2007) with markedly prolonged dry periods in wetlands. These hydrological changes imply potential modifications in the populations and metacommunities dynamics, and different patterns between organisms with different dispersion mode or ability are expected (Pyke, 2005; Sim et al., 2013; Boix et al., 2016).

The Age of Enlightenment for Temporary Wetlands? From Negative Perception to Valued Resource

The conservation status of many temporary wetlands around the world is attributable to a long-held negative perception of temporary wetlands. As mentioned earlier, while some ancient cultures in arid and semiarid regions had historic knowledge of temporary wetlands and valued them as part of their heritage, in modern societies these same wetlands are generally viewed more as wasteland or a liability (e.g., as sources of diseases or undesirable animals such as mosquitoes, or a loss of agriculture or developable land) than as valuable assets (Batzer and Boix, 2016; Jeffries et al., 2016). Moreover, the ecological value of individual temporary wetlands has increased as conversion of wetlands to other land uses has increased their rarity in the landscape. Additionally, temporary wetlands have historically received limited scientific attention and, even in some cases, perceptions of the ecology of these habitats are incorrect as conclusions were not evidence-based but rather were extrapolated from studies on permanent wetlands and wetlands in other climates, or were directly compared to permanent wetlands. Despite this, evidence to date suggests that temporary wetlands, by nature of their unique environmental conditions, contribute to beta and gamma diversity (Williams, 2000; Boix et al., 2008; Calhoun et al., 2017). To further complicate our understanding of this system, some scientific ideas on how temporary wetlands function had been established without direct documentation. Results from direct study of temporary wetlands open the door to a different perspective: predation could be an important biotic driver for community structure (Brendonck et al., 2002; Boix et al., 2006; McLean et al., 2016); drought is not a determinant environmental filter in all temporary wetlands because many species are adapted to drought (Biggs et al., 1994; Williams, 1996); and hydroperiod duration is not always the main hydrological factor to explain community composition, because in Mediterranean regions flooding timing could play a more determinant role (Kneitel, 2014; Boix et al., 2016).

Peer-reviewed literature on temporary wetlands is limited prior to the mid-twentieth century (Williams, 2006; Grillas et al., 2010; Jeffries et al., 2016). Using the words of Prof. William D. Williams (1985), "Despite the obvious ubiquity, ecological

importance and limnological interest of temporary waters, most limnological texts have little to say about them". In fact, for this reason Prof. D. Dudley Williams named temporary wetlands as "the Cinderellas of aquatic science"—in other words, the ugly and neglected little sister of the more charismatic, larger wetlands (Williams, 2006). However, an increase in scientific interest of temporary wetlands is evident for the following reasons (Blaustein and Schwartz, 2001; Williams, 2006):

- temporary wetlands are ubiquitous and many of them small, making them ideal subjects for pure and applied research studies;
- temporary wetlands can support a wide range of studies because they can be more readily manipulated for experiments, and their abundance allows for replication;
- temporary wetlands contribute to general understanding of "ephemerality" phenomena in terms of ecosystem functioning, community structure, and population dynamics of biological adaptations;
- temporary wetlands are inland environments characterized by high physical variability, and this variability drives both molecular and morphological evolution;
- temporary wetlands harbor disease vectors;
- temporary wetlands significantly contribute to aquatic biodiversity;
- temporary wetlands contain an important proportion of land-water ecotone;
- temporary wetlands have played a key role in biogeographical processes, because they served as postglacial dispersal routes.

Other investigators have noted additional wetland contributions of scientific importance, which include the following:

- temporary wetlands could be important study systems for explaining the origins of life, as earliest life forms may have arisen in shallow ponds (Ranjan et al., 2019);
- temporary wetlands represent an example of faunal complexes persisting over millennia with locally adapted endemic species (Keeley and Zedler, 1998);
- temporary wetlands are characterized by a unique combination of isolation and connectedness at different spatial scales, which can result in the evolution of endemic species (Zedler, 2003);
- temporary wetlands play a significant role in global cycles (Downing, 2010; Obrador et al., 2018), especially in C cycling through C storage and through emitting CO₂ (Holgerson, 2015; Holgerson and Raymond, 2016; Marcé et al., 2019); and
- temporary wetlands are an ideal habitat to study metacommunity dynamics because they configure networks of aquatic patches inside a terrestrial matrix with a reduced time window for species dispersal (Jeffries et al., 2016; Tornero et al., 2018; Cunillera-Montcusí et al., 2019).

Improved social awareness of the functions and values of and increases in scientific interest in temporary wetlands suggest perceptions of this resource are changing (Angeler, 2009; Brock, 2009; Calhoun et al., 2014b). The latter is demonstrated by the rising number of publications as journal articles (Fig. 3), monographs or proceedings of workshops or symposia (e.g., Diget and Rioux, 1998; Witham, 1998; Blaustein and Schwartz, 2001; Fraga, 2009; Bagella et al., 2016), and textbooks or chapters on temporary

Fig. 3 Number of papers published every year (p/y) from 1940 to 2019 in which the following terms are included in the title: "temporary wetlands," "temporary ponds," "temporary pools," "ephemeral wetlands," "ephemeral ponds," "ephemeral pools," "vernal ponds," and "vernal pools". Data extracted in July 2019 from the data base "Web of Science" (Clarivate Analytics). The top boxes show the mean number of publications per year for each decade.

wetland ecology (e.g., Williams, 2006; Alfonso et al., 2011; Lake, 2011; Boix et al., 2016; Jeffries et al., 2016) or conservation (e.g., Grillas et al., 2004; Calhoun and deMaynadier, 2004, 2008; Fraga et al., 2010; Sancho and Lacomba, 2010; Díaz-Paniagua, 2015).

Why Are Temporary Wetlands Ecologically and Socially Important?

Biogeochemistry and Hydrology

Gaps in our knowledge about the distribution and abundance of small waterbodies, or temporary wetlands, have been long neglected (Downing et al., 2006), and not surprisingly, so has the role of these wetlands in global cycling of matter (Downing, 2010; Hunter et al., 2017; Golden et al. 2019). Part of this can be explained by the relatively small size of most temporary wetlands, but their neglect can also be explained by the temporary nature of their ponds, making the wetlands themselves perceived as being temporary landscape features (Grillas et al., 2004; Boix et al., 2016; Van der Kamp et al., 2016). Ironically, it is this very characteristic of alternation between dry and wet phases of temporary wetlands that makes them crucial biogeochemical hotspots compared to surrounding upland systems. For example, dry wetlands substantially contribute to CO₂ emissions and have long been known as sources of CO₂, whereas inundated wetlands acted either as a source or a sink of atmospheric CO₂ (Catalán et al., 2014; Holgerson, 2015; Obrador et al., 2018). These CO₂ emissions have only recently been included in global estimates of CO₂; the first published estimates reveal a significant contribution of temporary systems (Marcé et al., 2019). Other biogeochemical functions of temporary wetlands include denitrification, sediment retention, pesticide transformation, and absorption of phosphorus and other aquatic pollutants (Zeng and Arnold, 2013). Temporary wetlands provide a disproportionately large fraction of wetland edges, and biogeochemical and other wetland functions tend to be enhanced in areas of wetland-edge (Cohen et al., 2016). Temporary wetlands also have a relevant role in some processes at a landscape or even a regional scale. For example, vernal pools in central Maine, United States, function as hotspots of leaf litter decomposition, denitrification and enzyme activity compared to adjacent upland forest sites (Capps et al., 2014).

In terms of their hydrology, temporary wetlands are known to be “nodes in hydrologic networks connecting landscapes in four dimensions—longitudinal, lateral, vertical, and through time” (Rains et al., 2016). Networks of temporary wetlands exist along a continuum of hydrologic connectivity from relative hydrologic isolation to predicted connectivity (Leibowitz et al., 2008; McLaughlin et al., 2014). Many temporary wetlands reduce peak floodwater flows, contributing to groundwater recharge or discharge (Euliss et al., 2004; Ganesan et al., 2016) and providing stream base flow. Temporary wetlands also provide lag, sink, and source (contribution) functions (as summarized by Rains et al., 2016) and “spill and fill” and “spill and merge” functions (Leibowitz et al., 2016) that have effects on the physical, chemical, and biological status of downstream waters.

Biodiversity

Temporary wetlands support a unique assemblage of biota adapted to living in temporary waters and hence contribute disproportionately to the biodiversity of both aquatic and semi-aquatic animals and plants (Williams, 2000; Herault and Thoen, 2009; Pinto-Cruz et al., 2009) by harboring rare and endemic taxa (Collinson et al. 1995; Marsh and Trenham, 2001; Calhoun et al., 2017; Mushet et al., 2019). In France, for example, vernal pools represent 0.05% of the natural habitats but hold around 35% of rare species and 5% of the protected plant species (Sajaloli and Limoges, 2001). The European Habitats Directive (European Directive 92/43/CEE) considers “Mediterranean temporary ponds” a priority habitat to conserve, but the Directive defines this wetland type strictly by the presence of particular plant species (European Commission 2003; Bagella et al. 2007). Moreover, obligate temporary species (i.e., some branchiopods) are examples of extremely rare species only known from selected ponds around the world (Alonso and García-de-Lomas, 2009; Cottarelli et al., 2010).

In addition to supporting rare and exclusive species, temporary wetlands also maintain metapopulation structure of many faunal groups, due to their importance as a foraging resource or breeding habitat (Griffiths, 1997; Wissinger, 1997). Many terrestrial mammals, amphibians, reptiles, and birds use the abundant resources in pools (i.e., egg masses, amphibian larvae and adults, invertebrates, algae and plants) to supplement their diets, especially following winter in temperate and boreal regions (Paton, 2005). Further, the absence in temporary wetlands of biotic groups not well adapted to drought allows the success of other biotic organisms susceptible to predation or competition (Wellborn et al., 1996). For example, the absence of fish (with few exceptions fish are not adapted to temporary waters; but see Pazin et al., 2006; Laufer et al., 2009; Lanés et al., 2014) in temporary wetlands increases the abundance and richness of invertebrate and amphibian specialists groups (Jeppesen et al., 2001). Fish predation may be a key factor in the structuring of communities (e.g., Brooks and Dodson, 1965; Brucet et al., 2010; Compte et al., 2011) and the flora and fauna of temporary wetlands in the absence of fish illustrates this well. Lastly, temporary wetlands also support biota that are terrestrial (Lott, 2010), or neither fully terrestrial nor fully aquatic (Jeffries et al., 2016). These additions to biodiversity are often overlooked in freshwater ecological studies (Mushet et al., 2019).

At landscape scales, temporary wetlands increase biodiversity through the addition of an aquatic feature (ephemeral to semi-permanent) in a terrestrial matrix that otherwise might include only permanent aquatic features. Temporary wetlands serve as aquatic stepping stones in an upland matrix and provide foraging and resting habitat for facultative species migrating to other resources. For example, in Europe, the agile frog (*Rana dalmatina*) can breed in different temporary ponds depending on the year (Guyétant, 1997), similarly the palmate newt (*Lissotriton helveticus*) can disperse across a network of temporary wetlands within a forest matrix (Isselin-Nondedeu et al., 2017). In the United States, the northern leopard frog (*Lithobates pipiens*) and bullfrog

(*Lithobates catesbeianus*) overwinter in deep-water habitats, migrate to temporary wetlands for reproduction or feeding, and then return to deep-water habitats to hibernate (Mushet et al., 2013). Additionally, Mushet et al. (2019) found that over long temporal periods, the number of taxa accumulate and therefore contribute to biodiversity at a greater rate in wetlands with temporary ponds compared to those with more permanent water regimes.

Socioeconomic

Temporary wetlands provide valuable ecosystem services including wildlife habitat, nutrient flux to adjacent ecosystems, flood control, water filtration, and cultural services (e.g., Turner et al., 2008; Gascoigne et al., 2011; TSSC, 2012). For example, prairie potholes provide breeding habitat for over 50% of all North American duck populations, despite covering only a tiny portion of the area of their range (Baldassarre and Bolen, 2006), and support extensive recreational and educational opportunities. Gilgais are used by grazers to graze seasonally stock in areas that lack permanent water (Lachlan Riverine Working Group, 2016). Soaks associated with rocky outcrops, gnamma holes and gilgais were an important source of water for indigenous communities as they enabled people to forage seasonally over areas that lacked permanent water (see Fitzsimons and Michael, 2017). Given the connections between social, economic, and ecological importance of temporary wetlands, scientific advances documenting the range of ecological functions provided by these resources create opportunities for enhanced understanding and documentation of their socioeconomic importance (Bauer et al., 2017).

What Are the Current Threats and Management Challenges?

Inconsistent and Inadequate Regulatory Protections

The lack of rigor and consistency in regulatory protections for small aquatic resources is a global phenomenon (Acuña et al., 2017). For example, in Europe, Canada, and the United States many wetlands are exempt from regulation based on size or size of impact or are not regulated at all (see the European Water Framework Directive; Clean Water Act and Food, Conservation, and Energy Act of 2008 in the US; Mushet et al., 2014; Creed et al., 2017). In addition, wetland regulations typically target the wetland depression with little regard to adjacent terrestrial ecosystems or connectivity to other critical wetland resources (Cohen et al., 2016). Some small aquatic resources do receive enhanced protections, but such protections are afforded to a small subset of the resources (Bagella et al., 2007; Zacharias and Zamparas, 2010; Mushet et al., 2014; Levesque et al., 2019). The cumulative, landscape scale impacts of loss of small, temporary wetlands are not currently addressed in regulatory frameworks (Jansujwicz and Calhoun, 2017).

Climate Change

The tight relationship between hydrology and temporary wetlands makes them extremely vulnerable to changes in climate. By virtue of their small size (high watershed to surface area or volume ratio) and temporary hydroperiods, temporary wetlands are very responsive to changes in temperature and precipitation patterns (Fig. 2). The International Panel on Climate Change's predictions for the next 100 years suggest that temperature increases will be greatest in high latitudes, precipitation amounts and patterns will change, frequency of extreme storm events will increase, and sea levels will potentially rise 20–60 cm (Junk et al., 2013). Responses to climate change will vary across a gradient from arid to boreal regions, from individual wetlands and types, and across species (Calhoun et al., 2017). For example, temporary ponds and their biota in Mediterranean climates are more threatened by reduced precipitation, increased salinity, and extended droughts than temperate or boreal temporary wetlands (Boix et al., 2016). Precipitation events may become more extreme in some areas coupled with seasonal changes in distribution (Junk et al., 2013). Repeated droughts will increase decomposition rates of soil organic matter and change the composition of the vegetation that may contribute to carbon storage (Hervé et al., 2019). Extreme shifts in aquatic invertebrate biodiversity (Sim et al., 2013; Renton et al., 2015) and plant species composition (Ghosn et al., 2010; Bagella and Caria, 2013) may occur in all temporary systems as a result of changes in climate patterns (wetlands and waterways).

Changes in Land Use

Temporary wetlands are small, dynamic, and vulnerable to land-use changes. Moreover, temporary wetlands are threatened by ecosystem loss and degradation associated with land change and land management activities, pollution, resource extraction, and invasive species. For example, conversion and use of lands for urbanization, agriculture, and livestock (switching temporary wetlands to permanent pools; Beja and Alcazar, 2003; Euliss and Mushet, 2004); water extraction; other human-mediated impacts to biodiversity, including sedimentation (Grillas et al., 2004); and toxic pollution (Collins et al., 2014) can result in the modification or destruction of temporary wetlands. In every continent, invasive species are a major threat to wetland biodiversity (Brinson and Malvarez, 2002; Zedler, 2004). Although the period of time without water impedes the colonization by exotic fishes, many exotic and specially adapted species have invaded temporary waters, including plants (Collinge et al., 2011; TSSC, 2012; Brundu, 2015), crayfishes (Carreira et al., 2014; Rodríguez-Pérez et al., 2014), and amphibians (Escoriza et al., 2014; Meilink et al., 2015). These invaders have contributed to the loss of species, wetland functions, food web dynamics, and habitat structure.

Management Challenges

Ecological

Temporary wetlands require management at both local and landscape scales; they are active biological, physicochemical, and ecological nodes in a terrestrial matrix (Grillas et al., 2004; Amis et al., 2009; Mushet et al., 2014; Golden et al., 2019). Since temporary wetlands are defined by hydroperiod, they are extremely susceptible to changes in land-use patterns and activities beyond the wetland footprint that alter hydrologic patterns. Because most temporary wetlands have high perimeter to surface area ratios and relative low volume with limited inlet and outlets, if present at all, they are also quite sensitive to alteration in chemistry from sediments and pollutants. In addition, many temporary wetlands support wildlife with biphasic or complex life histories involving annual migrations of hundreds of meters, making the adjacent terrestrial habitat an integral part of conserving their functions (Semlitsch, 2002; Bird and Day, 2014; Groff et al., 2017). Direct losses or fragmentation of wetlands, particularly ephemeral ponds, decreases wetland density increasing travel distances for biota, particularly those organized in metapopulations, using multiple aquatic resources (Gibbs, 1993).

Conservation of temporary wetlands ecosystems is made difficult by trends in conservation priorities, funding, and research that discount these resources (Martín-López et al., 2011) and therefore undercut scientific understanding of multi-scale processes. One major challenge is then to manage, conserve, or restore by integrating spatial scales from wetland to landscape, taking into account all fluxes of energy, materials and organisms. Clearly, one will not be able to manage for all things, but being aware of the implications of management is important at any scale.

Social

Limited public awareness of, incomplete understanding of the ecosystem services provided by, and cost:benefit issues associated with the conservation of temporary wetlands can complicate their management. For many temporary wetlands, public understanding of their functions is limited, diminishing support for public conservation actions (Mushet et al., 2014; Marton et al., 2015; Cohen et al., 2016). Two exceptions provide inspiration for addressing the challenge of limited public awareness. The importance of temporary wetlands in supporting breeding waterfowl in the Prairie Pothole Region is widely recognized and led to the region becoming known as the “duck factory of North America” (Lynch, 1984; Batt et al., 1989). Educational outreach has also helped to reverse some forestry practices detrimental to temporary ponds in the region of Chiron in France where it has been estimated that 90% of temporary wetlands were destroyed after intensive tree plantation and drainage (Couderc, 1979; Isselin-Nondedeu et al., 2013). Less visible ecosystem functions, however, such as biogeochemical and stream base flow support, are often not well-documented and are easily underappreciated or devalued (Millennium Ecosystem Assessment, 2005). Ecosystem services of temporary wetlands will have to be better quantified and explained to change perceptions of value and support for different management structures. The spatial mismatch between conservation benefits and costs can also challenge management of temporary wetlands. While the social importance of temporary wetlands can be quite significant (because they are the summation of many values held by society), temporary wetlands may offer individual landowners only limited private value relative to competing uses of lands. Management approaches that recognize the spatial distribution of benefits and costs and full extent of conservation costs are more likely to navigate these challenges successfully (Shogren et al., 2003; Bauer et al., 2010, 2017; Jansujwicz et al., 2013; Sunding and Terhorst, 2014; Levesque et al., 2016).

Public valuing of temporary wetlands could lead to enhanced inventories. To effectively manage temporary wetlands, it is essential to have a spatially explicit inventory and assessment of their ecological status and the context of the terrestrial matrix (Van Meter et al., 2008; Van den Broeck et al., 2015). Still, detailed wetland inventories are lacking in large sections of the world (e.g., China, South America, Russia), and small wetlands are often disregarded or not captured in places where inventories are conducted (Robertson and Fitzsimons, 2004; Junk et al., 2013). In addition, information may be available but poorly accessible and dispersed across agencies or private entities. If wetlands are mapped remotely, the ability to identify these features will vary greatly depending on the nature of the matrix. For example, in forested landscapes containing vernal pools in midwestern and northeastern North America, remote detection is problematic, often missing as much as 30% of pools (Tiner et al., 2015; Dibello et al., 2016). Even in open areas, remote detection of small wetland features can be limited by atmospheric conditions or spatial resolution of the sensor being used (Rover and Mushet, 2015). However, as technologies continue to improve (e.g., Wu and Lane, 2017), the ability to remotely detect and map small wetland features will continue to improve, especially with 3-D digital technology and high resolution LiDAR and Synthetic-Aperture Radar (SAR) approaches (Tiner et al., 2015; Wu and Lane, 2017).

Approaches for Conserving Temporary Wetlands

The most suitable approaches for conserving temporary wetlands include regulations or other forms of protection; sustainable management; collaborative conservation; and restoration and creation. Regulations or other forms of protection range from restrictive local protections conserving temporary wetlands and adjacent habitat to broader national regulations (e.g., the listing of the “Seasonal Herbaceous Wetlands [Freshwater] of the Temperate Lowland Plains” ecological community as critically endangered under national threatened species/communities legislation in Australia). Top-down regulation (at any government level)

has the advantage of setting clear rules but may suffer from lack of enforcement or “buy in” from the stakeholders being regulated. Protection may also result from crisis management of increasing threatened or rare temporary wetlands. For example, in southeastern Australia, ephemeral wetlands such as gilgais typically occur on fertile country which was privatized and suffered from conversion to more intensive agricultural activities. Efforts to increase the representativeness of Australia’s reserve system has seen the acquisition of a number of significant properties containing temporary wetlands (e.g., [Fitzsimons and Ashe, 2003](#); [Fitzsimons et al., 2004](#)).

Small natural features, including temporary wetlands, are arguably best managed using the meso-filter approach ([Hunter, 2005](#)), where features that may be small ecosystems in their own right or ecological elements within larger ecosystems can, by nature of their small size, open the door to sustainable management. Management approaches (including landowner incentives) will range from practices specific to land uses adjacent to temporary wetlands to landscape-scale approaches that recognize the functions of temporary wetlands as wetland complexes embedded in, and likely integral to, other ecosystems. For example, in arid and semi-arid Australian rangelands, gilgai conservation was considered a key feature in market-based incentives for landholders to better manage grazing ([Smyth et al., 2007](#)). In southeastern Australia, market-based auctions for conservation actions have been in place for the past decade and would prioritize ephemeral wetland communities due to their conservation status based on past loss and ongoing threats. Integration of vernal pools as a component of forest biodiversity is a way to manage sustainably both terrestrial and aquatic habitats. In many national forests in France and commercial forests in the northeastern United States, the application of best management procedures includes reducing disturbance immediately adjacent to pools by implementing management zones around the pools and implementing standards for maintaining uneven aged forest stands ([Calhoun and deMaynadier, 2004](#); [Guittet et al., 2015](#)).

Similarly, a market-based approach has been developed in New England, United States, to manage vernal pools in developing landscapes. A creative, voluntary, hybrid approach—a community based collaborative effort that draws from both top-down (a regulatory “stick” or incentive) and bottom-up regulatory restrictions—has generated great interest as a new conservation tool ([Freeman et al., 2012](#); [Calhoun et al., 2014b](#); [Levesque et al., 2016, 2019](#); [McGreavy et al. 2016](#)). In this program, impacts to pools in developing areas generate fees from developers to conserve vernal pool landscapes in rural areas in the same town (Special Area Management Plan for Vernal Pools in US Army Corps of Engineers Region 1; [Levesque et al., 2016, 2019](#)).

Collaborative voluntary approaches may evolve without the regulatory “stick.” For example, in Australia, collaborative landscape-scale arrangements such as Conservation Management Networks (biophysical networks of remnant vegetation sites across a variety of tenures and a social network of managers, owners, and interested people) have also been applied in fragmented landscapes containing temporary wetlands ([Edwards and Fox, 2013](#); [Fitzsimons et al., 2013](#)). These arrangements seek to (a) increase the protection status of sites; (b) maintain, enhance and re-establish remnants across private and public land; (c) bring together owners and managers of vegetation remnants; (d) connect and buffer remnant patches; and (e) develop consistent and complementary management across sites, and are across tenures.

Sustainable management in the face of climate change necessitates approaches that, as [Beier et al. \(2015\)](#) recommend, conserve “nature’s stage.” This approach moves conservation away from focusing on dynamic targets such as community types, e.g., spruce-fir forests or wood frog breeding pools, to capturing the physical features that support the array of defining characteristics of any given ecosystem target. For temporary wetlands, this would mean conserving an array of hydrogeomorphic settings (ones that support short to long hydroperiods in different physical settings) to allow a range of biogeochemical and water quality functions as well as support of diverse biota ([Marton et al., 2015](#)); this approach increases the chances that species and processes can evolve with changes in climate. In addition, the importance of allowing for gene flow among diverse temporary pool communities is highlighted by [Rice and Emery \(2003\)](#) and others who advocate for maintaining or restoring microevolutionary processes to meet the challenges of a shifting climate.

Restoration or creation of temporary wetlands ([Fig. 4](#)) may result from legal restrictions on impacts that require mitigation for wetland losses or from voluntary efforts to ameliorate losses. An inability to recreate hydrology is often the cause of a failure in restoring or creating temporary wetlands, particularly for pool-breeding amphibians and invertebrates ([Petranka et al., 2007](#); [Calhoun et al., 2014a](#); [Drayer and Richter, 2016](#)). In the North American Prairie Pothole Region, efforts to restore plant communities of temporary wetlands typically result in communities of lower floristic quality compared to plant communities of undisturbed wetlands ([Mushet et al., 2001](#), [Salaria et al., 2019](#)), but successes in plant restoration have been reported in other regions of the United States ([Ferren and Hubbard, 1998](#)). In gilgai depressions in southeastern Australia, increased floristic biodiversity occurred with removal of grazing, while gilgai microrelief homogenized by cultivation showed some recovery after release from cultivation ([Nolan et al. 2018](#)). In addition, landscape setting and condition and location with respect to other aquatic resources is important to wetland functions. It is challenging to recreate natural wetland functions in off-site areas that might not be conducive to natural wetland conditions.

In situations where wetland losses are high, wetland restoration or creation may be a good option. For example, efforts to restore vernal pools in France and Spain have attempted to create short hydroperiods by digging shallow pools that are very dependent on precipitation. Initial results concerning abiotic functions and amphibian colonization are promising ([Ruhí et al., 2012](#); [Isselin-Nondedeu et al., 2013](#)). However, even after relatively long periods post restoration, communities and ecological functions in many temporary wetlands are often not entirely restored ([Ruhí et al., 2009](#); [Matthews and Spyreas, 2010](#); [Moreno-Mateos et al., 2012](#); [Ruhí et al., 2016](#), [Salaria et al., 2019](#)). Creating temporary wetlands where they previously did not exist is an even greater challenge.

Fig. 4 Examples of temporary wetland restoration projects developed in NE of Iberian Peninsula. Left side, creation of temporary ponds to reinforce amphibian populations in Esplet, La Selva, Spain (photos: A. Ruhí). Right side, restoration of the “Bassa del Pla dels Rosers” in Albera, Alt Empordà, Spain (photos: M. Pascual and J. Montaner).

Acknowledgments

This research was supported by National Science Foundation award EPS-0904155 conferred to Maine EPSCOR. We thank Eduardo Gonzalez, Vincenc Acuña, Maria Felipe Lucia, and Malcolm Hunter for providing early reviews of the manuscript from which this chapter was based (i.e., Calhoun et al., 2017). Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Abstract

This article represents an assessment of Mariana Island Wetlands that includes the current status, stressors, and future viability. Wetlands in the Mariana Islands are comprised of the following categories: estuarine wetlands, forest wetland/swamps, freshwater marshes, lakes, and artificial wetlands. Wetlands have been significantly impacted by human habitation in the islands, with many degraded, fragmented, or lost due to development, invasive species, fire, erosion, altered hydrology, agriculture, and pollution. Hydrophytic vegetation is primarily composed of species of grasses, reeds, ferns, and trees. Wetlands provide habitat for some species listed as endangered, while a couple of species reliant on wetlands have been extirpated. Variables considered in analyzing current condition and future scenarios include stressors as well as conservation efforts. Considering the vulnerability of the wetlands and limited representation across the islands, as well as climate-related changes, it is anticipated that these habitats will continue to degrade in the absence of intensive or consistent management into the future.

Introduction

This document is an overview of wetlands that occur in the Mariana archipelago and describes the ecological factors that influenced them over time. Wetlands do not occur on all the islands: Guam contains the largest number and hectares of wetlands in the Marianas but wetlands also occur on Rota, Tinian, Saipan, Anatahan, and Pagan (Figs. 1 and 2; Table 1). All the islands are volcanic in

Fig. 1 Approximate locations of wetlands by type on the islands of Guam and Rota, Mariana Islands (see Table 4).

origin. The older islands in the south (Guam, Rota, Tinian, and Saipan) are primarily elevated coral limestone and weathered basalt (Mueller-Dombois and Fosberg, 1998), while the younger northern islands, including Anatahan and Pagan, are primarily volcanic and some have active volcanos (Ohba, 1994). An introduction to the Mariana archipelago including geography, hydrology, island names and descriptions, and climate can be found in Harrington et al. (2019). Another biome publication that references wetlands in the Mariana Islands is "Mariana Islands Coastal Ecotype" (Plentovich et al., 2019).

Wetland Description

Wetlands are lands that are permanently or periodically saturated with water, which impacts the nature of soil development and what animals and plant communities live in the soil and on its surface (Cowardin et al., 1979). Wetlands in the Mariana Islands function similarly to wetlands in other locations, for example, as flood storage, groundwater recharge, nutrient cycling, and buffer

Fig. 2 Approximate locations of wetlands by type on the islands of Tinian, Saipan, Anatahan, and Pagan in the Mariana Islands (see Table 4).

Table 1 Estimated wetland habitat and percentage of land cover in the Mariana Islands (Reeves and Amidon, 2018).

Island	Area in hectares	Area (% of Island)	Area (% Archipelago)
Guam	443	1	<1
Rota	4	<1	<1
Tinian	14	<1	<1
Saipan	182	2	<1
Anatahan	101	3	<1
Pagan	24	<1	<1

areas. Wetlands are also one of the most productive ecosystems in nature (Guam Coastal Management Program, 1991). In the Mariana Islands, wetlands are also crucial for the conservation and recovery of the Mariana Common Moorhen (*Gallinula chloropus guami*), locally known as pulattat. This endemic subspecies was listed as endangered in 1984 mainly due to the drainage/loss of suitable habitat (USFWS, 1984). The nganga' or Mariana Mallard (*Anas platyrhynchos oustaleti*), another endangered subspecies endemic to the Mariana Islands, was also reliant on wetlands, and is now extinct (USFWS, 1977, 2004). The bako or White-browed Crake (*Porzana cinerea*) was also apparently restricted to marshy areas on Guam and has also been extirpated, disappearing around the same time as the draining and development of much of the freshwater habitat on the island (Baker, 1951; Jenkins, 1983). Another species, the endangered ga'ga karisu or Nightingale Reed-warbler (*Acrocephalus lusincia*), while not an obligate wetland species, is typically found in most wetlands on Saipan (Marshall and Worthington, 1996) and has been extirpated from Guam, where it was primarily restricted to wetlands (Baker, 1951; Reichel et al., 1992).

Wetland determination is made on the basis of three factors, vegetation, soil, and hydrology (Cowardin et al., 1979; DEQ, 1997). Under this classification system, a wetland must have one of three attributes: (1) the land predominantly supports hydrophytes (a plant growing in water or on substrate that is periodically deficient in oxygen resulting from excessive water content) at least periodically; (2) the substrate is primarily undrained hydric soil (soil that is wet long enough to periodically result in anaerobic conditions, influencing the growth of plants); and (3) the substrate is non-soil and is saturated with water or covered by shallow water at some time during the growing season each year (Cowardin et al., 1979).

The vegetation found in the different types of wetlands in the Mariana Islands varies, and may depend on for example, saltwater influences, local disturbances, cultivation of crops, and whether they are permanent or ephemeral. In the Mariana Islands hydrophytic vegetation is primarily composed of species of grasses, reeds, ferns, and trees (Liske-Clark, 2015). Though not a complete list, Table 2 lists plant species commonly found in wetlands in the Mariana Islands. On Guam, wetlands have the lowest proportion of endemic species of all the major plant habitats, with widespread natives and a high proportion of nonnative species (Lee, 1974). Lee (1974) postulates this may be due to the fact that the wetlands on Guam are generally small and have a patchy distribution. Table 3 lists animals commonly found utilizing wetlands in the Mariana Islands.

Prehuman Condition

There are no known wetland range estimates for the Mariana Islands. Information on wetlands across the Mariana archipelago prior to human settlement is very limited. It has been generally believed that people arrived in the Mariana Islands between 3500 and 4000 years ago, but more recent information indicated they arrived as early as 4300 (Athens and Ward, 2004; Athens et al., 2004; ERCE, 1990). For example, pollen samples acquired from core sample taken from a small coastal wetland on the west side of Guam showed an entirely forested area (Athens and Ward, 2004; Athens et al., 2004). A core from a sinkhole in a site on Saipan (Kagman) that was a wetland during prehuman times shows that the vegetation prior to 4520 was characterized by mixed

Table 2 Common plant species found in wetlands in the Mariana Islands (ERCE, 1990; Fosberg, 1960; GDAWR, 2006; Moore et al., 1977; Raulerson and Rinehart, 1992; Stemmermann, 1981; Stinson, 1993; Stone, 1970; Vogt and Williams, 2004; Wiles and Ritter, 1993).

Scientific name	Chamorro, common name	Vegetation type	Wetland category ^a	Native or nonnative
<i>Acrostichum aureum</i>	Langayao, Swamp fern	Fern	Obligate	Native
<i>Avicennia marina</i>	Gray mangrove	Mangrove	Obligate	Native
<i>Barringtonia racemosa</i>	Langasat, Fishkill	Tree	Facultative ^b	Native
<i>Bruguiera gymnorhiza</i>	Mangle lahe, Oriental mangrove	Mangrove Tree	Obligate	Native
<i>Ceratopteris thalictroides</i>	Water fern	Fern	Obligate	Native
<i>Cocos nucifera</i>	Niyog, Coconut Palm	Tree	Facultative ^c	Nonnative
<i>Cyperus</i> spp. (<i>C. javanicus</i> , <i>C. odoratus</i> , <i>C. polystachyos</i>)	Cyperus	Sedge	Obligate?	Native
<i>Eleocharis ochrostachys</i>	Spike rush	Sedge	Obligate	Nonnative
<i>Hibiscus tiliaceus</i>	Pago, Beach Hibiscus	Tree	Facultative ^b	Native
<i>Hydrilla verticillata</i>	Waterweed	Herb	Obligate	Nonnative
<i>Ipomea aquatica</i>	Kangkun, Swamp morning glory	Vine	Obligate	Nonnative
<i>Ludwigia octovalvis</i>	Titmo, Primrose willow	Forb/Herb	Obligate	Nonnative
<i>Panicum purpurascens</i>	Para grass	Grass	Facultative	Nonnative
<i>Paspalum vaginatum</i>	Seashore paspalum	Grass	Obligate	Nonnative?
<i>Phragmites karka</i>	Karisu, Phragmites	Reed grass	Obligate	Native
<i>Polygonum minus</i>	Mamaka, Smartweed	Herb	Obligate	Native
<i>Rhizophora mucronata</i>	Mangle hembra, Red mangrove	Mangrove	Obligate	Native
<i>Rhizophora apiculata</i>	Mangle	Mangrove	Obligate	Native
<i>Scirpus littoralis</i>	Bulrush	Sedge	Obligate	Nonnative

?, not entirely clear that this species was introduced.

^aObligate—A plant that occurs in wetlands 99% of the time. Facultative—A plant equally likely to be found in wetlands as nonwetlands.

^bFacultative—A plant that occurs in wetlands between 67% and 99% of the time.

^cFacultative—A plant usually found in nonwetland conditions, but 1%–3% of the time is found in wetlands.

Table 3 List of animals that are commonly found in Mariana Island wetlands (Englund, 2011; Jenkins, 1983; Marshall Jr., 1949; Polhemus and Richardson, 2019; Pratt et al., 1987; Reichel and Glass, 1991; Richardson et al., 2009; Stinson, 1993; Vogt and Williams, 2004; Wiles and Ritter, 1993; A. Marshall, pers. obs.).

Scientific name	Chamorro name, common name	ESA listing status	Native, nonnative, or migratory
Herons/egrets/bitterns			
<i>Ixobrychus sinensis</i>	Kakkak, Yellow Bittern		Native
<i>Egretta sacra</i>	Chuchuko atilong, Pacific Reef Heron		Native
<i>Bubulcus ibis</i>	Chuchuko a'pak, Cattle Egret		Migratory
Waterfowl			
<i>Anas oustaleti</i>	Nganga', Mariana Mallard	Extinct	Native
<i>Anas acuta</i>	Northern Pintail		Migratory
<i>Aythya fuligula</i>	Tufted Duck		Migratory
Water birds			
<i>Porzana cinerea</i>	Bako, White-browed Crake	Extirpated	Native
<i>Gallinula chloropus guami</i>	Pulattat, Mariana Common Moorhen	Endangered	Native
Shorebirds			
<i>Pluvialis fulva</i>	Dulili, Pacific Golden Plover		Migratory
<i>Heteroscelus incanus</i>	Dulili, Wandering Tattler		Migratory
<i>Heteroscelus brevipes</i>	Dulili, Siberian (Gray-tailed) Tattler		Migratory
<i>Actitis hypoleucos</i>	Dulili, Common Sandpiper		Migratory
<i>Numenius phaeopus</i>	Kalalang, Whimbrel		Migratory
<i>Arenaria interpres</i>	Dulili, Ruddy Turnstone		Migratory
Other birds			
<i>Acrocephalus luscini</i>	Ga'ga Karisu, Nightingale Reed-warbler	Endangered	Native
Mammals			
<i>Rattus</i> spp.	Rats		Nonnative
Reptiles and amphibians			
<i>Varanus indicus</i>	Hilitai, Monitor (Mangrove) lizard		Nonnative
<i>Littoria fallax</i>	Kairo', Eastern dwarf tree frog		Nonnative
<i>Bufo marinus</i>	Kairo', Marine toad		Nonnative
<i>Trachemys scripta</i>	Red-eared slider		Nonnative
<i>Boiga irregularis</i>	Brown treesnake		Nonnative
Fish			
<i>Awaous guamensis</i>	Atot, Mariana goby		Native
<i>Stiphodon elegans</i>	Atot, Green riffle goby		Native
<i>Gambusia affinis</i>	Mosquito fish		Nonnative
<i>Oreochromis mossambicus</i>	Mozambique tilapia		Nonnative
<i>Clarius macrocephalus</i>	Itot, Catfish		Nonnative
<i>Poecilia reticulata</i>	Guppy		Nonnative
<i>Cichla ocellaris</i>	Tucanare		Nonnative
Insects			
<i>Limnogonus fossarium skusei</i>	Water-strider		Native?
<i>Anax guttatus</i>	Pale-spotted emperor dragonfly		Native
<i>Orthetrum sabina</i>	Slender skimmer dragonfly		Native
<i>Plantala flavescens</i>	Globe skimmer dragonfly		Native
<i>Tramea transmarina</i>	Red glider dragonfly		Native
<i>Agriocnemis femina femina</i>	Variable wisp damselfly		Native

?, not entirely clear that this species is native.

grassland and forest (Athens et al., 2004). These data show a change in vegetation with forest disappearing and grasses predominating on Saipan and with savanna and grassland pollen increasing on Guam at the time of the presumed appearance of humans (Athens and Ward, 2004; Athens et al., 2004). Cores obtained at American Memorial Park on Saipan included *Acrostichum* spores indicative of marsh conditions and which currently occur there today (Jarzen and Dilcher, 2009). Other species that commonly occur in various Mariana Islands wetlands today and that occurred in the cores, were *Bruguiera gymnorhiza*, *Cyperus* spp., and pollen from a *Hibiscus* comparable to *Hibiscus tiliaceus* (Jarzen and Dilcher, 2009; Table 2). Cloud Jr. et al. (1956) suggest that geologically, Lake Susupe and the surrounding marshes are barred-off lagoon remnants created by limestone sand deposits. The brackish lake is about 1066.8 m inland from the Philippine Sea (Wong et al., 1990). Cultural evidence suggests that Lake Susupe and/or its associated marsh areas may have been more extensive in the past (Thomas and Price, 1980). Paleohabitat evidence from Guam also shows changes in coastal habitat associated with changes in sea level and human use of the areas, and changes in sea level also affected the growth of mangrove forests, sedge-dominated wetlands and other coastal and low-elevation habitats (Carson, 2011). In the Marianas, measurements indicate a 1.8 m higher sea level dated 3400 through 1050 BCE that was followed by a draw-down over several centuries (Dickinson, 2000, 2003; Kayanne et al., 1993).

There is also little information on the effects of stochastic events for the Mariana Islands prior to human contact. There is evidence of sea level changes in the Mariana Islands (Carson, 2011) and on Rota there is evidence that there was a wetland prehistorically (Becker and Butler, 1988; Stinson et al., 1991), but the extent of prehistoric impacts are not known. Prior disturbances due to typhoons or floods may have been minimal as the species and habitats adapted to those conditions.

Habitat Viability of Prehuman Wetlands: Resiliency, Representation, and Redundancy

Habitats sustain through resiliency, redundancy, and representation. The viability of wetland habitat depends on maintaining multiple and distributed habitat types (redundant) of sufficient quality and size (resilient) with species richness and genetic range (representative) to survive across its ecological environment over time. The phrase “ecologically healthy” refers to functions affecting biodiversity, productivity, biochemical cycles, and evolutionary processes that are linked to the climatic and geologic conditions in the region (Karr, 1991 and Karr et al., 1986 in Naiman et al., 1992). The ecologically healthy, or viable, wetland habitat that existed prior to human contact likely maintained natural connections between system components. Native biota that was historically characteristic of wetlands in the Mariana Islands filled environmental niches necessary to sustain the habitat.

Resilience is defined as the amount of disturbance that the system can absorb without a change in structure and composition (Carpenter et al., 2001; Holling, 1973). Disturbance in wetland habitat include natural forces such as typhoons, floods, drought, and sea level change. Due to hydric soils and highly adapted flora and fauna in the wetlands, “healthy” wetlands would have had an increased capacity (high resiliency) to be able to recover from such stochastic and natural events.

Redundancy refers to the extent and range of a habitat across a given landscape. Redundancy from having multiple resilient wetlands can decrease the risk of loss. Habitats with few occurrences across the islands are less resilient to catastrophic events that might otherwise have a relatively minor impact on widely-distributed habitats (Stacey and Taper, 1992). It can be assumed that throughout the Marianas, wetlands were limited by both the presence of hydric soils and hydrology and therefore were on only found on the few islands which contained hydric soils, sufficient rainfall, and topography suitable for ponding water. Therefore, it is likely wetlands were only found on Guam, Tinian, Saipan, Pagan, and possibly Rota, before human contact.

The primary driving factor for maintaining a high level of representation for wetlands is related to dispersal and connectivity. Connectivity refers to the ability of plants and animals to move between habitat patches on the landscape (Hanski, 1998; Tischen-dorf and Fahrig, 2000). Wind, water, and birds are the most important natural dispersal vectors in the Marianas. Wind and ocean currents are particularly important for dispersal of vegetative propagules (plant structures such as fragmented runners or seeds) to disperse to distant sites. Biological connectivity is maintained through dispersal and considers whether species can move to similar or other suitable habitat. Migratory birds contribute to connectivity between wetlands at small to large scales (i.e., regional to inter-continental) while transiting between feeding, breeding, and nonbreeding areas (Buelow and Sheaves, 2015). Species mobility varies and results in different rates, patterns and scales of biological connectivity on the landscape (Taylor et al., 1993).

Table 4 summarizes the viability of wetlands in their historical state. These values are assumed based on what is known about these habitats in their native state. For instance, lakes likely recovered quickly from storms. However, there were relatively few lakes found across the archipelago and therefore had low redundancy and low representation. In contrast, marshes may have also had high resiliency, but also had higher redundancy and therefore higher representation.

Change from Prehuman Condition

The islands have been greatly altered due to the long history of human habitation. The prehistoric human impacts on the natural environment include the development of a savanna landscape in the interior upland areas of Guam and the decline in pollen of Guam’s native forest species (Athens and Ward, 2004). The data indicate a significant change in the appearance and natural history of Guam in around 2000 years due to early human settlement (Athens and Ward, 2004). There is limited direct pollen evidence for prehistorical agriculture, but taro, *Colocasia esculenta*, pollen was documented in a core suggesting it was likely grown in coastal wetlands around 1100 years ago (Athens and Ward, 2004). Additionally, sedimentary evidence indicates that there was an increase in coastal deposition resulting from erosion from the surrounding hillsides after 2400 cal. B.P. implying intensive use of the landscape, presumable for agriculture (Athens and Ward, 2004).

After Guam was “discovered” by Magellan in 1521, the islands have been administered by the Spanish, Germans, Japanese, and Americans, each culture importing crops and ornamental plants, as well as animals (Moore et al., 1977). Wetlands were used for rice

Table 4 Levels of resiliency, redundancy, and representation for wetlands that existed in the Mariana Islands prior to human contact.

Habitat type	Resiliency	Redundancy	Representation
Estuarine wetland	High	Low	Medium
Forest wetland/swamp	Medium	Low	Medium
Marsh	High	High	High
Lake	High	Low	Low

and taro cultivation, uplands were subjected to slash and burn agriculture, and during World War II, the southern islands were variously impacted by battles, runway construction, increased human population, and bombs (Engbring et al., 1986; ERC Environmental and Energy Services (ERCE), 1990; Moore et al., 1977; Stinson, 1993). After the war, large military installations were built on Guam and *Leucaena leucocephala* was seeded by the US military on Guam, Saipan, and Tinian (Engbring et al., 1986; Fosberg, 1960).

There are very few comprehensive studies of wetlands in the Marianas and much of the published information is included in vegetation or ornithological surveys across the archipelago (Fosberg, 1960; Moore et al., 1977; Tenorio and Associates, Inc., 1979). Two of the most detailed reviews of the wetlands on Guam and the CNMI were written by Wiles and Ritter (1993) and Stinson (1993) respectively. According to Wiles and Ritter (1993), significant losses of wetlands occurred historically on Guam, though they wrote that the extent of losses is difficult to quantify. For example, there was extensive destruction and alteration of wetlands by the US military in the Apra Harbor area between 1945 and 1950 when the Navy expanded port facilities there (Mueller-Dombois and Fosberg, 1998; Wiles and Ritter, 1993). As a result, mangrove communities along the eastern harbor and freshwater wetlands along the Sasa, Atantano, and Namo Rivers were destroyed (Wiles and Ritter, 1993). A coastal highway built around the southern half of Guam resulted in roadbeds built across wetlands and likely altered natural drainage patterns (Wiles and Ritter, 1993).

Current Condition

Based on the above, it is not likely that the original character of wetlands in the Marianas is preserved on any of the islands. The vegetation of the islands is so altered by humans that its original character has only been preserved in a few restricted locations, such as along cliffs (Spoehr, 1957). Clearly, the quantity of natural wetlands has significantly decreased. The area of wetlands totals 443 ha on Guam and 260 ha in the CNMI, which includes the area for a number of artificial wetlands (Table 5; Guam EPA, 2008; Reeves and Amidon, 2018). Natural wetlands in the Mariana Islands are mainly located in low elevation areas. Following are descriptions of the types of wetlands currently on each of the six islands.

Guam

Within the Mariana archipelago, Guam contains the largest number of wetlands (Guam Division of Aquatics and Wildlife Resources (GDAWR), 2006; USFWS, 1991; Wiles and Ritter, 1993). The majority of wetlands occur in the southern and central areas of the island (Fosberg, 1960; Fig. 1). In these areas, the clay or argillaceous limestone soils retard the percolation of waters, allowing surface waters to accumulate while the northern limestone plateau allows rapid water seepage such that few marshy areas occur in the north (Wiles and Ritter, 1993). Many of the wetlands in the interior are located along the upper drainages of river and small tributaries (Wiles and Ritter, 1993).

As noted, there have been significant losses of wetland on Guam historically, though the extent of losses has not been well quantified (USFWS, 1991, 2009; Wiles and Ritter, 1993). The 1983 National Wetland Inventory maps for Guam indicate there were around 2023 ha (5000 acres) of wetlands at that time, while current estimates are 443 ha (1094 acres) (Table 5; Guam EPA, 2008; Reeves and Amidon, 2018). Some of the losses were due to extensive destruction and alteration of wetlands by the US military around Apra Harbor due to the expansion of port facilities, some resulted due to the building of the coastal highway around the southern part of the island, and in the mid-1970s to mid-1980s, several sets of aquaculture ponds were constructed in wetlands along the Talofof, Agfayan, and Ajayan Rivers (Wiles and Ritter, 1993). Much of Agana Swamp was infilled to expand Agana

Table 5 Landownership and acreage of wetland habitat in the Mariana Islands (Reeves and Amidon, 2018).

Island	Land ownership ^a	Area in hectares
Guam	DoD	125
	NPS	0.4
	Private	167
	Public	35
	Unknown	113
Rota	Public	3
Tinian	DoD (leased)	13
	Unknown	0.4
Saipan	Private	76
	Public	105
Anatahan	Public	100
Pagan	Public	23

^aPublic land includes village or agricultural homesteads and lands in the CNMI leased to developers. Department of Defense (DOD) lands include lands owned by DOD on Guam and lands leased by DOD and leased back to farmers and ranchers on Tinian. NPS lands include lands leased by the National Park Service on Saipan. Unknown areas are those where ownership data is unavailable.

Village, including a shopping center built in 1978 (Ayers and Clayshulte, 1983; Wiles and Ritter, 1993). Other land development projects have increased resulting in additional wetland fills, however, regulatory agencies have been successful in reducing the number of wetland fills since then and protective regulations have improved (Wiles and Ritter, 1993). Wetlands have also been affected by pollution, agriculture, fires, and erosion. In addition, although karisu (*Phragmites karka*) is indigenous, it has infilled many wetlands, and reduced the ability to support a diversity of flora and fauna. Wiles and Ritter (1993) speculate that this indigenous species has been impacted by disturbances to the wetlands, increasing its abundance.

Estuarine wetlands are found in areas of tidal intrusion or brackish waters and consist primarily of mangroves. Mangroves on Guam are the most extensive and diverse in the Mariana Islands, although they total only around 2.25 ha (GDAWR, 2006). The largest areas of mangroves occur along the eastern shores of Apra Harbor (GDAWR, 2006; Wiles and Ritter, 1993). Atantano wetland is one of the largest wetlands on Guam and has freshwater as well as estuarine areas (Table 6; Wiles and Ritter, 1993). This large natural coastal wetland is located on the southeast side of Apra Harbor and has the most developed mangroves in the Mariana Islands (Wiles and Ritter, 1993).

Forest wetland/swamps occur along the edges of marshes, rivers, and in wet depressions in forests (Wiles and Ritter, 1993). This wetland type is dominated by woody vegetation, typically *Hibiscus tiliaceus*, however, the Taloforo River Valley is dominated by *Baringtonia racemosa* (Fosberg, 1960; Wiles and Ritter, 1993). This Forest wetland/swamp is the largest contiguous wetland on Guam located in the riparian areas along the Taloforo Valley and lower Ugam Rivers, and is unique for being the primary area used by the endangered Mariana Gray Swiftlet (*Aerodramus vanikorensis bartschi*) for foraging (Wiles and Ritter, 1993).

Freshwater wetlands are characterized by emergent, herbaceous vegetation (Stemmermann, 1981). There are a number of natural freshwater marshes on Guam (Table 6). They range in size from around 96 ha of marshland (Agana Swamp) to some that are less

Table 6 Wetland types found in the Mariana Islands (DEQ 1997; ERCE 1990; GVP 2019; Marshall and Worthington, 1996; Ritter, 1997; Stinson, 1993; Takano, 2003; Wiles and Ritter, 1993, USFWS 1991, 1996).

Island	Wetland-type				
	Estuarine wetland	Forest wetland/swamp	Freshwater marsh	Lake	Artificial wetlands
Guam	- Sasa Bay Wetland - Atantano Bay Wetland - Agfayan River Valley (forest wetland/swamp)	- Taloforo River Valley	- Agana Swamp - Naval Station Marsh - Namo River Marsh - Naval Magazine Marshes (3 marshes) - Sarasa Marsh		- Barrigada Ponding Basin - Masso Reservoir - Shell Oil Wetlands (4 ponds) - San Luis Ponds (2 estuarine ponds) - Pulantat Marshes (2 marshes) - Naval Magazine Pond - Fena Lake Reservoir - Assupian Marsh (ephemeral) - Yabai wetland (ephemeral)
Rota					- Rota Resort golf course waste water treatment ponds and water hazards
Tinian		- Marpo (also called Makpo) Wetland (no longer extant)	- Bateha Morning Glory Pond (seasonal)	- Lake Hagoi	- Mahalang Wetlands (bomb craters filled with water)
Saipan	- Sadag Tasi Mangroves	- American Memorial Park	- Susupe North Marshes - Susupe Potholes - Flores Pond (ephemeral) - San Roque Wetlands - Tanapag Wetlands - Chalan Kiya Wetland - Chalan Laolao Wetland - DanDan Wetland - As Lito Wetlands	- Lake Susupe	- Kagman Wetlands - LaoLao Golf Course - San Jose Golf Course - Price Costco/Power Center Wetland - Falig Mitigation Pond - Phrag Mitigation Pond - Annie's Pond (ephemeral) - Tank - Kingfisher Golf Course
Anatahan				- Caldera Lake - East Crater Lake	
Pagan				- Lake Sanhiyong (Lower Lake-brackish) - Lake Sanhalom (Upper or Inner Lake-freshwater)	

than 0.5 ha (Wiles and Ritter, 1993). These freshwater marshes tend to be dominated by very dense stands of karisu, but other types of vegetation occur, including other grasses, as well as sedges, and the fern *Acrostichum aureum* (Fosberg, 1960; GDAWR, 2006; Wiles and Ritter, 1993). Agana Swamp is the largest natural freshwater wetland on the island, but it is surrounded by development and the thick beds of karisu prevent other favorable plants from becoming established, reducing its attractiveness to wildlife, including the endangered pulattat (Wiles and Ritter, 1993).

Artificial wetlands on Guam were originally created as water impoundments for use by humans, cattle, and crops, including Fena Lake, Masso Reservoir (Fig. 3), and Pulantat Marsh, or to eliminate flooding in the surrounding area, such as Barrigada Ponding Basin (Table 6; Wiles and Ritter, 1993). Some of the sites are no longer used for their original purpose, but serve as important habitat for conserving the pulattat (Wiles and Ritter, 1993). The vegetation in these areas is variable, but karisu and pogo are usually minor components (GDAWR, 2006). Many of these sites are considered important in the conservation of the pulattat (Stinson et al., 1991).

Rota

Currently, there are no natural wetlands on Rota. The pulattat currently occurs at wetlands on Guam, Tinian, and Saipan, but has not been recorded historically on Rota (Baker, 1951; Engbring et al., 1986). In 1992, construction began on an 18-hole golf resort, that included a wastewater treatment plant and water features on the golf course (Fig. 1; Table 6). Wiles and Worthington (1996) noted that a variety of migratory birds were attracted to the site since its creation, and in 1995, adult and juvenile pulattat, were observed using the site (Worthington, 1998). Prehistoric evidence indicates that the pulattat once occurred on Rota (Steadman, 1992; Becker and Butler, 1988 cited in Steadman, 1992). Since the pulattat is an obligate wetland species, it is thought that wetlands occurred at one time on Rota but were lost due to human-related wetland loss or elimination of wetlands due to sea-level changes (Steadman, 1992; Stinson et al., 1991). Pulattat continued to be observed at the Rota Resort sites on occasion (Takano, 2003).

Tinian

Tinian has several wetland areas, Hagoi Marsh, Bateha Morning Glory Pond, Mahalang Wetlands, and Marpo Swamp (Fig. 2; Table 6). Historical literature indicates that Marpo Swamp was formerly open water used by a variety of waterfowl (Barratt, 1988; Northern Islands Company, 1989; cited in Stinson, 1993). Currently, Marpo is used a water source for the island and is heavily overgrown with *Hibiscus tiliaceus*, and no longer has open water (Engbring et al., 1986; A. Marshall, pers. obs). Batea Pond is a very small and seasonal marsh and Mahalang Wetlands are bomb craters filled with water (USFWS, 1996; A. Marshall, pers. obs). Lake Hagoi is a freshwater marsh about 15 ha in extent, but the amount of open water varies quite a lot depending on rainfall and it occasionally dries up during droughts (Engbring et al., 1986; Stinson, 1993; USFWS, 1996). Lake Hagoi is important habitat for the endangered pulattat (USFWS, 1996). The number of pulattat using Hagoi varies considerably with water level both being higher in the wet season (USFWS, 1996). Pulattat have been observed sporadically at Bateha and Mahalang Wetlands (USFWS, 1996). Ducks and other migratory species were frequently observed at Lake Hagoi and migratory species were occasionally observed at Bateha and Mahalang wetlands (USFWS, 1996).

Saipan

Wetland loss on Saipan has occurred through filling, cultivation of rice and sugar cane, and development, and the introduction of nonnative fish is believed to have altered the aquatic environment (Stinson, 1993; USFWS, 1991). There are numerous natural wetlands of various sizes mainly on the west coast of the island (Fig. 2).

American Memorial Park, administered by the National Park Service, is primarily forest wetland/swamp (Stinson, 1993). There are mangroves (*Bruguiera gymnorhiza*) and *Hibiscus tiliaceus* in the wetland, but this area has been heavily impacted by fill and waste

Fig. 3 Masso Reservoir, Guam. Photo credit: Greg Koob.

oil (Stinson, 1993). The wetland is a mosaic of marshy areas with *Acrostichum aureum*, open areas with emergent wetland vegetation, and mixed wet forest of *Hibiscus tiliaceus*, *Bruguiera gymnorrhiza*, and ironwood (*Casuarina equisetifolia*) (Johnson, 2003). There are also mudflats adjacent to the park and migratory shorebirds may be observed there (A. Marshall, pers. obs.). The forest/wetland area is utilized by the ga'ga karisu (Johnson, 2003; Mosher, 2006; Rauzon, 2010; Williams, 2007). Pulattat may also be observed in the wetland on occasion, though they not very common (Johnson, 2003; Rauzon, 2010; Williams, 2007; A. Marshall, pers. obs.). Fig. 4 shows an example of a *Hibiscus tiliaceus* dominated swamp on Saipan.

There are a number of freshwater marshes on the island, for example, Susupe Marsh Wetlands, Chalan Kiya (Fig. 5), DanDan Wetland (Fig. 6) and Flores Pond (Table 6). Many of these wetlands are predominantly karisu marsh areas and several are important for providing flood storage (DEQ, 1997). Some of the ephemeral wetlands, such as Flores Pond, are important to the pulattat because they don't have the invasive tilapia, which likely compete for food resources (Stinson et al., 1991).

Lake Susupe (Fig. 7) is the largest wetland in the Commonwealth of the Northern Mariana Islands (CNMI) and the lake and surrounding wetlands comprise over 60% of freshwater wetlands in the CNMI (Engbring et al., 1986; Stinson, 1993). Susupe Lake is believed to have been a coastal lagoon that was formed when sand blocked it off from the ocean (DEQ, 1997; Stinson, 1993). The lake occupies around 17 ha and is important for flood control and groundwater recharge (DEQ, 1997; Stinson, 1993).

Fig. 5 Photo of a marsh in Chalan Kiya Saipan. Photo credit: Tyler Willsey.

Fig. 6 DanDan Wetland, Saipan. Photo credit: Greg Koob.

Fig. 7 Susupe Lake, Saipan. Photo credit: Greg Koob.

Many of the artificial wetlands on Saipan, such as Kagman and the Price Costco wetlands (**Fig. 8**), have been created as mitigation due to fill of other wetlands resulting in habitat loss for the pulattat (DEQ, 1997; A. Marshall, pers. obs., 1996). In addition, there are also a number of ponds created by golf courses on the island, such as Kingfisher and LaoLao Bay Golf Course Ponds (**Fig. 9**), which are also used by pulattat and some migratory birds.

Anatahan

Anatahan is a stratovolcano (volcano built up of alternate layers of lava and ash) with an elongate caldera running 5 km east to west and 2.5 km north-south (Fig. 2, Rowland et al., 2005). There are two volcanic craters in the caldera, the western portion is an older center crater that had a vegetated central basin and a smaller eastern pit crater with steep sides, some vegetation, and bubbling mud pits at the base that were sometimes submerged in a shallow lake (Division of Fish and Wildlife (DFW), 2000; Kessler, 2011; Rowland et al., 2005). The island's volcano erupted in May 2003, its first historical eruption, followed by eruptions in 2004, 2006, and 2007 (Global Volcanism Program (GVP), 2019). The final eruption ended in 2008 (GVP, 2019). At some point following the eruptions, two lakes were observed in the caldera; the western Caldera Lake and the East Crater Lake (Table 6; Mapcarta, 2019). There are currently no known observations of vegetation or animals utilizing either lake.

Pagan

There are two lakes on Pagan, Lake Sanhiyong (Lower Lake or Lagoon Lake) which is brackish, and Lake Sanhalom (Upper or Inner Lake) which is freshwater (Table 6). The lakes are both located on the northern section of the island (Fig. 2). Lake Sanhiyong is on the west coast, separated from the ocean by a cinder beach, such that tidal influence is small, but waves sometimes wash over the beach during storms raising the level of the lake (Stinson, 1993). Lake Sanhalom is located on the western foot of Mount Pagan and had warm springs that emptied into the lake on the southeast shore (Stinson, 1993). Both lakes are considered geologically young and do not have developed marshes (Stinson, 1993). Wetland habitat has been drastically altered and reduced on Pagan (Reichel et al., 1992). Most of the vegetation that occurred around the lakes was destroyed in the 1960 and 1970s by introduced feral ungulates and in 1981, Mount Pagan erupted depositing thick layer of volcanic ash and cinders, and buried much of the vegetation that remained in and around the lakes (Stinson, 1993). Another factor that affected the ecology of the lakes was the introduction of the nonnative Mozambique tilapia (*Oreochromis mossambicus*) in the 1950s (Stinson et al., 1991). The fish occur in both lakes having survived the eruptions (Stinson, 1993). Both lakes have sparse emergent vegetation and are mainly surrounded by nonnative vegetation (A. Marshall, pers. obs.).

Primary Wetlands Stressors (Table 7)

Development and Altered Hydrology

Stinson (1993) states that development and drawdown for water use are the greatest threats to wetlands. Development can result in small- and large-scale filling of wetlands, bisecting sections of a wetland, run-off of polluted water, soil run-off, changes in vegetation, increased human access, increased access of feral cats (*Felis catus*) and dogs (*Canis familiaris*), and modified drainage patterns (Wiles and Ritter, 1993; Stinson, 1993; Stinson et al., 1991). Development has impacted most of the wetlands in the Mariana Islands. For example, Highway 1 (built around 200 years ago) on Guam divides Sasa Bay and Atantano wetlands into two areas

Table 7 Primary stressors affecting wetlands in the Mariana Islands.

<i>Human presence/abundance</i>	<i>Climate change</i>
Development and altered hydrology	Sea level rise, groundwater and marine inundation and flooding
Invasive plants and animals	
Water pollution	Typhoons
Recreation and human access	Drought
Erosion	Temperature
Fire	

acting as a dike and altering drainage patterns and likely salinity (Wiles and Ritter, 1993). Marpo wetland on Tinian is a prime example of a wetland extant in 1957 that no longer exists due to pumping of the water since the 1930s (Spoehr, 1957; Stinson, 1993; Stinson et al., 1991).

The populations in Guam and the CNMI have increased dramatically from 62,641 (1955) to 167,294 (2019) on Guam and from 7985 (1955) to 57,216 (2019) in the CNMI (Worldometers, 2019a, 2019b). The increase in population and increasing reliance on tourism (Wiles and Ritter, 1993; Stinson, 1993) has resulted in construction beyond just residential housing; roads, hotels, shopping malls, commercial buildings, parks as well as the facilities needed for support, including water, sewage treatment plants, landfill, seawalls, etc. Guam and the CNMI have been identified as two of 13 of the most developed small island international destinations characterized by visitor density (McElroy, 2003).

Invasive Plants and Animals

Table 8 lists the primary invasive species that impact wetlands and the species that utilize wetlands in the Mariana Islands. Islands are particularly susceptible to introductions of non-native species (Vitousek, 1988). The impacts of these species in wetlands varies considerably, for example, invasive rodents can directly alter the distribution, diversity and abundance of plants, and indirectly impact seed dispersers such as birds and invertebrates (Steadman, 1999; Wiewel et al., 2009; Wilson Rankin et al., 2018). Monitor lizards, however, are most likely to mainly impact birds, such as the pulattat. The species mostly likely to impact the wetland itself include invasive plants, which can reduce cover resulting in changes in water temperature, outcompete native species, or invade the wetlands reducing

Table 8 Primary invasive species that occur in Mariana Island wetlands.

<i>Common name</i>	<i>Scientific name</i>	<i>Primary species affected</i>	<i>How the species impacts the habitat</i>	<i>Where present</i>	<i>References</i>
Scarlet (Ivy) gourd	<i>Coccinia grandis</i>	Native vegetation	Blocks sunlight and smothers native plants	Guam, Tinian, Saipan	PIER (2019)
Bitter melon	<i>Momordica charantia</i>	Native vegetation	Blocks sunlight and smothers native plants	Guam, Tinian, Saipan	PIER (2019)
Chain of love	<i>Antigonon leptopus</i>	Native vegetation	Blocks sunlight and smothers native plants	Guam	PIER (2019)
Elephant grass	<i>Pennisetum purpureum</i>	Native vegetation	Reduces native habitat	Guam, Rota, Tinian, Saipan, Anatahan, Pagan	PIER (2019)
Mosquito fish	<i>Gambusia affinis</i>	Native invertebrates	Altered aquatic ecosystem	Guam, Tinian, Saipan	Stinson (1993)
Tilapia	<i>Oreochromis mossambicus</i>	Native vegetation, pulattat	Reduces native habitat, competes with pulattat for food, and may prey on chicks	Guam, Tinian, Saipan, Pagan	Wiles and Ritter (1993), Stinson (1993), Stinson et al. (1991)
Monitor lizard (Mangrove monitor)	<i>Varanus indicus</i>	Preys on birds and eggs	Reduces bird dispersers which affects vegetation dispersal	Guam, Rota, Tinian, Saipan, Pagan	Reed et al. (2010), Stinson (1993), USFWS, (1996, 2009)
Brown treesnake	<i>Boiga irregularis</i>	Preys on birds and reptiles	Reduces bird dispersers which affects vegetation dispersal	Guam	USFWS (1991)
Rodents	<i>Rattus</i> sp.	Native vegetation and birds	Depredates native flora and fauna	All islands	USFWS (1996)
Ungulates (pigs, goats, deer, carabao, cattle)	(<i>Sus scrofa</i> , <i>Capra hircus</i> , <i>Rusa marianna</i> , <i>Bubalus bubalis</i> , <i>Bos taurus</i>)	Native vegetation, birds	Depredates native fauna, impacts quality of wetlands through erosion, sedimentation, and input of waste	Guam, Rota, Tinian, Saipan, Pagan	Wiles and Ritter (1993), Stinson (1993), USFWS (1996)

the amount of open water, as well as feral ungulates, which can affect the quality of the water itself through sedimentation, waste products, trampling, foraging, and changes in water temperature, (Griffin et al., 1989; Henry, 2006; Merlin and Juvik, 1992; Morin, 1998; Stone, 1989; USFWS, 2015). One of the most impactful introduced species in the Mariana Islands is the brown treesnake (BTS, *Boiga irregularis*). The BTS was accidentally introduced to Guam shortly after WWII (Rodda et al., 1992). The BTS spread across Guam resulting in multiple impacts, including devastating the island's terrestrial fauna, as well as socioeconomic and human health impacts (BTTWG, 2015). The BTS caused the extinction or serious reduction of most of the islands resident bird species, including the ga'ga karisu (extirpated from Guam) and the Yellow Bitter, the latter which has apparently altered its breeding habitat from wetlands in the late 1970s to urban areas and islets by mid-1990 (Jenkins, 1983; Reichel et al., 1992; Wiles et al., 2003).

Water Pollution

Pollutants, for example, fertilizer, animal waste, pesticides, and heavy metals, can exceed the ability of a wetland to absorb such pollutants, leading to degradation, and may result in the death of invertebrates, fish, and birds using the wetland. Lowland wetlands may be susceptible to act as sinks for pollutants, meaning that pollutants tend to accumulate and potentially increase the toxicity with time. Pollutants can be deposited through urban and agricultural runoff, non-native ungulates, air pollution, and leakage from landfills and dumps. Wetlands in urban areas may be particularly susceptible as storm drains and roadside ditches may lead to streams and wetlands.

An oil spill at the mouth of the Laguas drainage of the Sasa Bay wetland in June 1980 occurred when oil leaked from a pipeline buried along Highway 1 that killed or damaged about 1.8 ha of mangroves (Wiles and Ritter, 1993). Currently, little is done to survey for toxicants in wetlands in the Mariana Islands.

Recreation and Human Access

Most of the wetlands in the Marianas are significantly impacted by human recreation due to their proximity to urban areas. Natural and artificial wetlands are often used as water sources for domesticated ungulates, golf courses, and for stocking nonnative fish, as well as areas to dump trash, and harvest vegetation such as kangkun (*Ipomea aquatica*) for consumption.

Erosion

Erosion may be caused by poorly planned development, clearing vegetation, careless construction practices, rooting, trampling, and overgrazing by ungulates, agriculture, fire, and building roads. In turn, erosion can result in excess sediment deposition, changes in native plant and animal communities by destabilizing substrates, damaging or destroying individual plants, altering hydrological patterns, and the shrinkage or loss of wetlands. Erosion is noted to have impacted a number of wetlands on Guam (Wiles and Ritter, 1993).

Fire

Fires caused by humans either intentionally (clearing of land or for hunting) or unintentionally (improper disposal of ignition sources) is relatively common. Fires remove vegetation from the landscape creating loose soils and ash, which after rain events, can cause large amounts of sediment to wash into rivers increasing turbidity and ultimately depositing it into wetlands. This infilling allows the encroachment of karisu and other grasses, and result in the decrease of open water habitat (Wiles and Ritter, 1993). Fires were noted to impact at least 9 of the wetlands on Guam listed in Table 4 (Wiles and Ritter, 1993). Reichel and Glass (1991) indicate the fires may have played a role in the decline of the ga'ga karisu at Agana Swamp.

Sea Level Rise, Groundwater and Marine Inundation and Flooding

Climate change is expected to result in changes in rainfall, storm intensity and frequency, temperature, and sea level rise. In fact, some of these changes are already occurring, including sea level rise and increasing surface air temperatures, and the impacts from these changes to various habitats are already being observed (Keener et al., 2012). Lowland areas are vulnerable to sea level rise, wave-over wash and saltwater intrusion (Keener et al., 2012) and the majority of wetlands in the Marianas Islands occur in lowland areas. As a result of increased inundation from high waves, coastal wetlands and mangrove areas are becoming more saline over time (Gilman et al., 2008). The increased salinity is expected to impacts the plants and animals that rely on freshwater resources (Keener et al., 2012). Seawater intrusion and flooding is also expected to negatively impact wetlands as well as contaminating aquifers and wells and damaging agriculture (Keener et al., 2012).

Typhoons

Typhoons are common in the region of the Pacific that includes the Mariana archipelago (Engbring et al., 1986). The impacts of typhoons include downed, damaged, and defoliated vegetation from intense wind, heavy rain and salt spray and mortality by salt water inundation in low-lying areas (Fosberg, 1960; Kerr, 2000). Salt water inundation can also have a negative impact on animal species that rely on freshwater wetlands, for example the pulattat which prefers freshwater wetlands (USFWS, 1991).

Drought and Increasing Temperature

Drought may result in reduced streamflow, evaporation of standing water, increased water temperature, and the loss of native riparian and wetland plants (Benning et al., 2002; Still et al., 1999). Guam and the CNMI have had fewer extreme one-day rainfall events in the past 60 years (Keener et al., 2012).

In the Western North Pacific, maximum and minimum air temperatures have shown upward trends in the past 60 years, though the variability is high (Keener et al., 2012). Increased temperatures may result in changes in vegetation composition, increased risk of forest encroachment, and accelerated decomposition rates, that have the potential to impact wetland habitats. Increased air temperatures are likely to result in increased water temperatures as well that would impact wetland reliant species.

Conservation Efforts

The impacts from stressors can be mitigated through laws and regulations, land protection, outreach, as well as restoration/management efforts, such as control of predators and invasive species, establishing buffers, and water management regimes. Land ownership of wetlands in the Marianas varies considerably by island (Table 5). For example, Lake Hagoi, the main wetland on Tinian, is located in the area leased by the U.S. Department of Defense (DOD). Under their Integrated Natural Resources Management Plan (INRMP), the pulattat is monitored annually at Lake Hagoi and Bateha wetlands to examine long-term population trends and changes in the wetland habitat (Naval Facilities Engineering Command (NAVFAC), 2019). A buffer zone and fire suppression measures may be added at a later date. The DOD also owns around 125.45 ha of wetlands on Guam and plans to eradicate feral pigs at the Camp Covington wetlands (Naval Facilities Engineering Command (NAVFAC), 2019).

The U.S. National Park Service (NPS) manages roughly 20.23 ha of hibiscus dominated swamp on Saipan as well as a small constructed marsh at American Memorial Park (Willsey, pers. obs. 2019). The CNMI Department of Land and Natural Resources (DLNR) purchased a 4.49 ha section of Lake Susupe in 1981 for the protection, restoration, and preservation of freshwater wetlands, habitat, and species. On Saipan, some artificial wetlands were created as mitigation for the loss of wetlands in other areas, for example, the Price Costco Wetland and Annie's Pond.

One of the main conservation efforts that occurs in the Mariana Islands is aimed at preventing the spread of the brown treesnake from Guam to the CNMI. To that end, the Brown Treesnake Technical Working Group (BTTWG) has written a biosecurity plan with objectives to prevent the BTS from getting off Guam, suppressing BTS numbers, and eradication from Guam (BTTWG, 2015).

Conservation efforts are also undertaken by both the CNMI DFW and the GDAWR. For example, DFW conducts surveys and research on the ga'ga karisu and GDAWR is working to preserve habitat for the pulattat. Both agencies conduct surveys and research on several species in order to better understand conservation needs. The University of Guam and the Northern Mariana Islands are also actively involved in research on invasive species as well as native species.

Laws and Regulations

Table 9 indicates a number of Federal and State Laws and regulations that protect wetlands in the Mariana Islands. These laws and regulations are vital in helping to minimize the impacts of the stressors on these wetlands. While Federal regulations apply across all jurisdictions, local laws differ between Guam and the CNMI. Biosecurity laws are widespread and are important due to the economic damage caused by invasive species, such as the brown treesnake.

Summary of Interactions and Conservation Efforts

The most significant stressors for wetlands are development and altered hydrology and the impacts of invasive species. At this time, conservation efforts and laws and regulations have not prevented declines in the quality or quantity of wetlands across the archipelago. For example, the Price Costco mitigation wetland on Saipan is currently not being managed as agreed on and the wetland has become overgrown with karisu, such that there is little open water remaining.

The need for increased levels of protection and restoration is significant, particularly with an increasing human population. The work of the local agencies and Universities may be expected to improve conservation efforts in the future.

Future Scenarios

The wetland habitat's response to four foreseeable future scenarios (Table 10) was evaluated out to the year 2035 (see Miller (2019) for the determination of foreseeable future). The condition of wetlands in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The CMPs are as follows:

Table 9 Federal and State laws and regulations impacting wetlands in the Mariana Islands.

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
Fish and Wildlife Coordination Act of 1958	1958	Federal	Enacted to protect fish and wildlife when federal actions result in the control or modification of a natural stream or body of water. 1958 amendment includes a requirement that other federal agencies coordinate with the USFWS about proposals that have an impact on wetlands.
Sikes Act and the Integrated Natural Resources Management Plan	1960	Federal	Directs the U.S. Department of Defense to carry out conservation and natural resources rehabilitation on military installations in coordination with local and federal fish and wildlife agencies. Amendments to the Act required installations to create an Integrated Natural Resources Management Plan (INRMP) to describe future and ongoing conservation projects on military lands.
Land and Water Conservation Fund Act	1965	Federal	Federal program established to provide funds and matching grants to federal, state and local governments for the acquisition of land and water, and easements on land and water, for the benefit of all Americans.
Clean Water Act	1972	Federal	Establishes the basic structure for regulating discharges of pollutants into the waters of the United States and regulating quality standards for surface waters.
Endangered Species Act	1973	Federal (USFWS and NMFS)	Protects critically imperiled species and their habitats from extinction.
50 CFR 16	1974	Federal	Implements the Lacey Act (18 USC 42), which prohibits importation of injurious species.
Convention on International Trade in Endangered Species	1975	International	Ensures that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild.
Executive Order (EO) 11987	1977	Federal	Charges Executive agencies with restricting the introduction of exotic species into the natural ecosystems on federal lands; and encourages States to do the same.
Executive Order 11988	1977	Federal	Requires federal agencies to avoid to the extent possible the long and short-term adverse impacts associated with the occupancy and modification of flood plains and to avoid direct and indirect support of floodplain development wherever there is a practicable alternative.
Executive Order 11990	1977	Federal	Issued to “minimize the destruction, loss or degradation of wetlands and to preserve and enhance the natural and beneficial values of wetlands.” To meet these objectives, this EO requires federal agencies, in planning their actions, to consider alternatives to wetland sites and limit potential damage if an activity affecting a wetland cannot be avoided.
Fish, Game, and Endangered Species Act, Public Law (PL) 3–47	1981	CNMI	Authorizes the designation of endangered species and critical habitat and established the Division of Fish and Wildlife and contains fish and wildlife regulations.
Commonwealth Environmental Protection Act, PL 3–23	1982	CNMI	Established the Division of Environmental Quality (DEQ) and includes regulations for water quality certification, waste water discharge, as well as earth-moving permit systems.
Coastal Resources Management Act, PL 3–47	1983	CNMI	Established the Coastal Resources Management Office and contains regulations and standards for activities permitted in “Wetland and Shoreline Areas of Particular Concern” (APCs).
Emergency Wetlands Resources Act	1986	Federal	Authorizes the use of money from the Land and Water Conservation Fund for the purchase of wetland habitat by the Secretary of the Interior. Prior to this Act, the purchase of wetlands by the Federal Government had been prohibited.
Public Land Exchange Act, PL 5–33	1987	CNMI	Includes the framework for the acquisition of land for public purposes, including wetland protection, through exchange for public land.
Executive Order 13112	1999	Federal	Requires that a Council of Departments dealing with invasive species be created to prevent the introduction of invasive species and provide for their control and to minimize the economic, ecological, and human health impacts that invasive species cause.

Table 9 Federal and State laws and regulations impacting wetlands in the Mariana Islands.—cont'd

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
An Act to Amend the Guam Environmental Protection Agency Guam Soil and Erosion and Sedimentation Control Regulations, PL 25–152	2000	Guam EPA	The purpose of these regulations is to control accelerated soil erosion, thereby preventing the pollution of Guam's waters (wetlands, streams, and rivers) from fertilizers, pesticides, sediments and other polluting substances carried by sediment, and to protect property and to promote the public health, safety and welfare by regulating grading, clearing, grubbing and stockpiling, and by setting minimum standards for erosion and sedimentation control for the island of Guam.
Northern Mariana Islands Administrative Code Chapter 65–30, § 65–30-005	2014 Amendment	CNMI DEQ	The purpose of the regulations and technical provisions in this chapter is to establish certain minimum standards and requirements as determined by the Division to be necessary for control of nonpoint source runoff from human-related activities. Specifically, these regulations are designed to: (1) Protect marine and fresh water quality; (2) Maintain and enhance beneficial uses of marine and fresh waters; (3) Promote public awareness of the importance of protecting the CNMI's marine and fresh water resources from siltation, and bacteriological, and chemical contamination; and (4) Protect public health by protecting and enhancing the quality of marine and fresh water recreational and traditional fishing sites.
Executive Order 13751	2016	Federal	To prevent the introduction of invasive species and provide for their control, and to minimize the economic, plant, animal, ecological, and human health impacts that invasive species cause (amends EO 13112).
7 CFR 360.200	2018	Federal	Designates certain plants as noxious weeds.

Table 10 Four foreseeable future scenarios considered in this Mariana Islands wetland assessment.

<i>Future scenario</i>	<i>Description</i>
Future scenario one	Status Quo—The most likely foreseeable future, no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future
Future scenario two	A slight increase in natural resource conservation in the CMPs marginally improves conservation management
Future scenario three	A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management
Future scenario four	A moderate to large increase in conservation actions in the CMPs substantially improves conservation management

- (1) *Conservation Values*: stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) *Laws and Biosecurity*: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented (e.g. hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) *Development or Conservation Planning*: national, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

Scenario 1: Status Quo

This scenario is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. Under this scenario, there would be no change to implementation of the three CMPs between 2019 and 2035 (Table 11). An increasing human population and increased development, land, and water use is expected on the inhabited islands and therefore habitat stressors are expected to increase at a small annual rate. Development is likely to continue to result in direct fill of small scale

Table 11 Responses of stressors on wetlands in the Mariana Islands in foreseeable future scenarios.

Conservation Management Parameters (CMPs)				
Conservation Values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of <i>natural resource conservation and biosecurity</i> (NRC/B) within laws and development or conservation plans.			
Laws and Biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented.			
Planning for Development or Conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation).			
Foreseeable future scenarios and the resulting wetland conditions				
Use Foreseeable Future	Scenario One	Scenario Two	Scenario Three	Scenario Four
Scenario One as a “baseline” to characterize changes in	CMPs: unchanged in support for NRC/B.	CMPs: small increase in support for NRC/B.	CMPs: small to moderate decrease in support for NRC/B.	CMPs: moderate to large increase in support for NRC/B.
Conservation Actions and Habitat Conditions in Future Scenarios Two, Three and Four.	Conservation Actions: no change; current rate of land cover change continues through the foreseeable future. Habitat Condition: habitat area, quality, and sustainability slowly decrease through the foreseeable future.	Conservation Actions: marginal increase. Habitat Condition: habitat area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future.	Conservation Actions: substantial decrease. Habitat Condition: urban and agricultural uses are prioritized over conservation; habitat area, quality, and sustainability substantially decrease through the foreseeable future.	Conservation Actions: substantial increase. Habitat Condition: robust, sustained effort to restore, manage, and expand conservation; habitat area, quality, and sustainability substantially increase through the foreseeable future.
Habitat Stressors				
Human Presence/Abundance	Responses of wetland stressors			
Development	Small to moderate increase	No change (redevelop)	Moderate to large increase	Small to moderate decrease
Altered hydrology	No change to small increase	No change	Larger increase	Small decrease
Recreation/access	Small increase	Small increase	Larger increase	Larger increase
Water pollution	Small increase	No change	Larger increase	Small decrease
Invasive species	Small increase	Small increase	Larger increase	Small decrease
Fire	Small to moderate increase	Small increase	Larger increase	No change to small decrease
Erosion	Small increase	No change	Larger increase	Small decrease
Climate				
Temperature	Small to moderate increase	Small to moderate increase	Small to moderate increase	Small to moderate increase
Precipitation	Small decrease	Small decrease	Small decrease	Small decrease
Sea Level	Small increase	Small increase	Small increase	Small increase
Storms	Small increase	Small increase	Small increase	Small increase

wetlands, increased fires, and erosion. Laws and biosecurity CMPs are expected to remain unchanged while human development continues to grow, resulting in the potential for new invasive species while existing invasive species will likely continue to spread. A slight decline in the quality and quantity of natural wetlands may be expected, while artificial wetlands may slightly increase due to increased need for water for new developments, including golf courses and sewage treatment plants.

We envision the increased fill of wetlands will facilitate the encroachment of karisu decreasing open water habitat. Drought will also continue to allow for the encroachment of karisu by decreasing open water habitat. Overall, this scenario will likely result in continued degradation of natural wetlands that will negatively impact the species that rely on them.

Scenario 2: There Is a Slight Increase in the CMPs that Marginally Improves Conservation Management

Under this scenario, conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas. This scenario may be considered status quo but with minor improvements in the CMPs (Table 11). While human populations increase, development would not increase substantially, however, increased water needs could still impact the hydrology of wetlands on inhabited islands. With improved biosecurity, the risk of new introduced species arriving will be slightly reduced, but the extant species on the islands might still be expected to increase in number and range. For example, feral pigs and deer would continue to contribute to erosion on Guam by impacting vegetation in the watershed through rooting and grazing of bank stabilizing plants increasing soil erosion and wetland fill. We envision if significant damages to the watershed are occurring, natural resource agencies will attempt to reduce or eliminate the cause whether it be reducing ungulate numbers in key areas or increasing awareness of the impacts of fire. Feral ungulates are not currently in high enough numbers to cause significant impacts to wetlands on Saipan, but it could become an issue in the future, and could have impacts on Tinian and Pagan.

Even with improved natural resource conservation, this scenario could still result in a slight decline in the quality and quantity of natural wetlands but to a lesser extent than scenario one. The status of artificial wetlands may remain unchanged from Scenario 1.

Scenario 3: There Is a Small to Moderate Decrease in Conservation Actions in the CMPs that Substantially Decrease Conservation Management

Under this scenario, all natural resource management actions in the CMP are set aside in deference to land use of economic development. While localized management may allow some wetlands to continue to exist, a significant decline in the quality, quantity, and ecological function of wetlands and the species that rely on them would be expected. An expanded human population will further require increased land and water use to the detriment of wetlands. Weakened biosecurity measures in this scenario are expected to result in increased invasive species as well as an increase in the number of invasive species that currently occur on the islands.

Under this scenario, feral ungulates will increase in numbers in the CNMI and will begin having impacts to wetlands similar to those seen in Guam. The incidence of fire will increase and will result in significant effects to wetlands by increasing the amounts of loose soil vulnerable to erosion during rain events. There would be no planning or management to try and address climate-related changes, further adding to the negative impacts on wetlands.

Scenario 4: There Is a Moderate to Large Increase in Conservation Actions in the CNMPs that Substantially Improves Conservation Management

Scenario four is an overt and robust, active, ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of natural wetlands, and to actively restore and expand them. Under this scenario, increased support and emphasis on natural resource conservation would result in management to restore these habitats. Development would no longer be expected to result in the direct fill of wetlands as responsible urban planning would leave these areas undeveloped and increasingly rely on re-development instead. Improved implementation of biosecurity regulations and removal of invasive species from habitats that are negatively impacted would improve the habitats.

Fire, as a significant contributor to erosion in the Marianas, would be the focus of a robust effort by regulatory agencies. Outreach campaigns informing the public of the damage fires may cause and monitoring of high risk areas by law enforcement and regulatory agencies would greatly reduce the frequency and intensity of fires in the Marianas. Under this scenario existing artificial wetlands may be modified and vegetated to more closely resemble natural wetlands, providing higher quality habitat for wildlife. In addition, the creation or enhancement of wetland systems in the lower reaches of key watersheds for water quality and coral reef enhancement are likely to occur under this scenario.

Summary

Based on this analysis, it is likely that wetlands in the Mariana Islands will decline without intensive conservation management efforts (Table 11). Scenarios one, two, and three are likely to result in fragmentation, degradation, and loss of natural wetlands as well as in declines of species due to the stressors. Under scenario four, improved and more robust sustained conservation efforts will help mitigate the impacts of stressors, but climate-related changes may be expected to continue. Additional exploration will likely be needed to determine how to best mitigate climate-related changes.

Abstract

Capture fisheries production is no longer increasing, and production of fish, shrimp, and molluscs by aquaculture is necessary to meet the global demand for aquatic food animals. Aquaculture is conducted in freshwater areas, brackishwater areas, and in the ocean. Most fish production from aquaculture is in freshwater areas, and freshwater fish are reared mainly in ponds. The global, freshwater pond surface area was estimated at 8.8 million ha in 2004. Since 2004, freshwater aquaculture production has doubled; but, because the intensity of production has increased, the global pond area in 2016 was estimated to only be around 11 million ha. Nevertheless, the freshwater pond aquaculture area and volume is great enough for it to be included in the freshwater biome. The impact of aquaculture on the freshwater biome appears mostly negative, because aquaculture ponds tend to be eutrophic and of low biodiversity. Aquaculture pond effluents also are enriched in nutrients and organic matter and can cause eutrophication in receiving water bodies. As with agricultural production, which also has many negative environmental impacts, aquaculture production is necessary to supply the human population with food. Efforts to make food production more resource-use efficient and less harmful to the environment are critical to society.

Introduction

Fish, shrimp, and other aquatic animals are an important source of food and especially of animal protein for humans. According to the Food and Agriculture Organization (FAO) of the United Nations (FAO, 2018), 20.2 kg (live weight equivalent) capita⁻¹ of aquatic animals were consumed globally in 2015. While the average consumption of 21.6–25 kg capita⁻¹ of fisheries products was similar among North America, Europe, Asia, and Oceania (Australia and South Pacific Islands), the average annual consumption in Africa was only 9.9 kg capita⁻¹. By economic status, average annual consumption was 7.7 kg capita⁻¹ in low-income, food-deficient countries, 20.5 kg capita⁻¹ in other developing countries, and 24.9 kg capita⁻¹ in developed countries. At present, aquatic animals provide 17% of animal protein for human consumption (FAO, 2018).

Fish culture in ponds was possibly practiced as many as 4000 years ago in China and Egypt. The earliest known document on the topic is from China and dated 475 BCE; it was written by Fan Li and entitled *Fish Breeding* (Stickney, 2000). Fish and shrimp culture has been practiced for many centuries in China, Japan, and other Asian countries, and carp culture in Europe apparently began with the Romans and spread into central and eastern Europe where carp farms have been common since the 1600s and 1700s (Balon, 1995; Stickney, 2000).

The prospects for aquaculture were vastly improved by development of hatchery methods for producing fish and shrimp for stocking in ponds. It also was discovered that primary productivity and fish production in ponds could be increased by applying fertilizers to promote the growth of natural food organisms for culture animals. Acidic ponds could be limed to enhance response to fertilizers. Manufactured feeds were developed that allowed greater production of aquaculture animals than possible in fertilized ponds. Finally, it was also discovered that more feed could be applied (and greater fish and shrimp production realized) if mechanical aerators were used to aerate pond water and prevent low dissolved oxygen concentrations. Much of this knowledge about pond aquaculture management was developed between 1900 and 1980. Nevertheless, aquaculture did not contribute much to global fisheries production until the capture fisheries reached or possibly exceeded its sustainable limit in the late 1980s. The stagnation of capture fisheries has led to further improvement in aquaculture technology and a trend of increasing aquaculture production (Fig. 1).

Global Aquaculture Production

Capture fisheries production is somewhat greater than aquaculture production (Fig. 1), but roughly 20 million tonnes (Mt) of the capture fisheries are used annually for nonfood purposes; mainly for fish meal and oil production. Aquaculture production, which

Fig. 1 Global fisheries and aquaculture production. Data from FAO FishStat (www.fao.org/fishery/nems/38200/en).

is used almost exclusively for human consumption, accounted for 53% of fisheries products for human consumption in 2016 (FAO, 2018). Some question the reliability of the FAO fisheries statistics and claim that capture fisheries still produces more food for human consumption than does aquaculture (Edwards et al., 2019), however it is not disputed that aquaculture makes a major contribution to global fisheries production and that future increases in fisheries production must come from aquaculture. The FAO fisheries statistics, for better or for worse, are the most comprehensive dataset available and often the only data available for a particular assessment of aquaculture production.

The global production and utilization of aquatic food animals by capture fisheries and aquaculture are summarized (Table 1). In 2016, freshwater bodies provided only 12.8% of capture fisheries production, while 64.2% of aquaculture production was from inland (mostly freshwater) culture systems. Aquaculture production in 2016 consisted of 54.1 Mt. of finfish (mostly from freshwater), 17.1 Mt. of molluscs (mostly from the ocean), and 7.9 Mt. of crustaceans (mostly from brackish or ocean waters). There also was 0.94 Mt. of other aquatic animals to include sea cucumbers, turtles, sea urchins, jellyfish, etc., which came mostly from marine waters. In addition, 30.1 Mt. of aquatic plants were farmed mainly in the ocean (FAO, 2018). Total aquaculture production was 110.2 Mt. of which 80.0 Mt. were fish, molluscs, and crustaceans.

The amount of aquaculture varies greatly by continent, by country, by region within a country, and within a region. Asia is the leading aquaculture continent with 89.40% of global production in 2016. Percentage of production by other continents were Europe, 3.67%; South America, 3.38%; Africa, 2.48%; North America, 0.81%; Oceania 0.26%. Production was reported for a total of 192 countries in 2016 (FAO, 2018), but 10 countries produced 94% of inland global production (Table 2). Much of the production in several of these countries was not freshwater production or was not done in ponds.

Several hundred species of fish and other aquatic organisms are produced by aquaculture, but relatively few species make up most of the production. The major species produced by pond aquaculture and their 2016 production are given in Table 3. Most of the whiteleg shrimp and milkfish production is from coastal ponds filled with seawater or brackishwater. While the FAO database does not report aquaculture production from ponds separately, FAO (2018) emphasizes that ponds are the main freshwater aquaculture production method. According to data presented by Verdegem and Bosma (2009), 92.6% of freshwater aquaculture

Table 1 Global production by capture fisheries and aquaculture of fish, crustaceans and molluscs in 2016.

<i>Production category</i>	<i>Live weight quantity (million tonnes)</i>
Inland capture fisheries	11.6
Marine capture fisheries	79.3
Total capture fisheries	90.9
Inland aquaculture	51.4
Marine aquaculture	28.7

production was from ponds, and at least 90% of the 2016 production also is likely from ponds. Some inland aquaculture production is done in ponds filled with low-salinity surface water or with saline groundwater from wells (Roy et al., 2010). This production is not great, but it is not completely separated from the freshwater production in the FAO database.

Freshwater Pond Area

Records of aquaculture pond areas are not maintained by some governments, and most governments that maintain such records seldom update the data. The most reliable estimate of the global aquaculture pond area is probably that of Verdegem and Bosma (2009). They placed the total water surface areas of freshwater and coastal, brackishwater aquaculture ponds in 2004 at 8,750,509 ha and 2,332,737 ha, respectively. Their data suggested that 92.6% of freshwater aquaculture production and 17.5% of marine aquaculture production (including brackishwater) was derived from ponds, and annual production intensity was 2.89 and 1.42 t ha⁻¹ for freshwater and brackishwater ponds, respectively.

Table 3 Major species produced by pond aquaculture and global production of each in 2016.

Species	Production (million tonnes)
Grass carp, <i>Ctenopharyngodon idellus</i>	6,068,000
Tilapia spp.	5,377,000
Silver carp, <i>Hypophthalmichthys molitrix</i>	5,301,000
Common carp, <i>Cyprinus carpio</i>	4,557,000
Bighead carp, <i>Hypophthalmichthys nobilis</i>	3,527,000
Carassius spp.	3,006,000
Catla, <i>Catla catla</i>	2,961,000

Wuchang bream, <i>Megalobrama amblycephala</i>	826,000
Cyprinidae	670,000

FAO FishStat (www.fao.org/fishery/nems/38200/en).

Freshwater (inland) production in 2016 was 51.37 Mt. of which at least 90% was from ponds. The amount of area necessary for this production at the estimated 2004 production intensity of 2.89 Mt. ha⁻¹ would be 16.00 Mha. However, aquaculture production in ponds is becoming more intensive. For example, statistics collected by the US Department of Agriculture (https://www.nass.usda.gov/Surveys/Guide_to_NASS_Surveys/Catfish_Production/index.php), revealed that between 2004 and 2016, the intensity of ictalurid catfish production in the United States roughly doubled increasing from 3.86 to 7.91 t ha⁻¹. Production of other species also is increasing, and there may have been much less increase in the global aquaculture pond water surface area since 2004 than suggested by the straight-line interpolation above.

Fairly reliable data on the coastal shrimp farm area are available because of the environmental controversy concerning the conversion of mangrove forest areas to shrimp ponds. Aquacultured shrimp production is exclusively from ponds; it increased by 106.2% between 2004 and 2016, but the global shrimp pond area increased by only 18.6% (Boyd and McNevin, 2015). The intensity of shrimp production in ponds increased from 1.31 t ha⁻¹ in 2004 to 2.28 t ha⁻¹ in 2016. The production of freshwater aquaculture increased by 89.0% between 2004 and 2016. Assuming the intensity of freshwater production increased at a rate similar to marine shrimp production, the increase in freshwater pond aquaculture area would not have exceeded 25% and the 2016 area likely was around 11.0 Mha.

Ponds require more land than the land covered by the water impounded in them. Embankment ponds require land beyond water edges, canals may be used to convey water from other water bodies into embankment ponds, some farms may have reservoirs in which source water is held before introduction to ponds, and settling basins may be necessary to assure compliance of farm discharge with effluent quality standards. Aquaculture farms also require land for buildings, roads, parking, and staging areas.

The amount of land that is necessary for embankments and other farm-level earthen infrastructure increases the land required on aquaculture farms. The ratio of the total area devoted to aquaculture on a farm to the production pond water surface area is called the land to water ratio (LWR). A satellite imagery study of 100 aquaculture farms (2783 production ponds) in 26 countries (Jescovitch et al., 2016) revealed that the LWR was on average 1.48, i.e., each 1-ha increment of production water surface area required 0.48 ha of additional land at the farm level. The LWR may be calculated with the following equation:

$$\text{LWR} = 1.5583X^{-0.102}$$

where X = the average area of the production ponds on an aquaculture farm (ha).

Based on the average LWR and a global freshwater pond water surface of 11 Mha, the total area devoted to freshwater pond aquaculture would be 16.3 Mha. This area is roughly equal to the areas of Suriname or Tunisia or the states of Florida or Wisconsin in the United States.

Types of Aquaculture Ponds

Aquaculture ponds usually are of one of three types. The most common type is made by building embankments around an area in which water is confined. Soil usually is removed from the area to become the pond bottom and used as earthfill for the embankments. Embankments normally are 2–3 m high, 2–5 m wide at the top, and side slopes of embankments are 1:1 (vertical:horizontal) to 1:3 depending upon soil characteristics (Fig. 2). Embankments and pond bottoms are thoroughly compacted to minimize the potential for seepage, and pipes or various types of concrete water gates with dam boards installed to convey water into and out of ponds. Pond bottoms are gently sloped toward the water exit structure to facilitate complete draining at harvest. Embankment ponds are ideal for aquaculture because their water levels may be maintained and controlled. Embankment ponds usually can be drained and refilled as needed to fit the management schedule.

Fig. 2 Cross-section of an aquaculture pond embankment.

A watershed pond is constructed by building an embankment (dam) across a watershed to retain stream flow, overland flow, or both. Watershed ponds typically have a standpipe and a drain pipe extending through the bottom of the dam for establishing the water level and discharging excess inflow. A spillway with its bottom at a slightly higher elevation than the top of the stand pipe usually is included at one end of the dam to avoid water overtopping the dam after periods of unusually large inflow. In dry weather, water levels may decline drastically in watershed ponds—particularly in those without stream inflow.

Excavated ponds are constructed by digging a basin which is usually filled by rainfall and surface storm flow. Some excavated ponds may extend below the top of the water table and fill partially by groundwater inflow. The soil excavated to produce such ponds is either piled around the pond or disposed in another area. These ponds typically fill in the rainy season, but their water levels may be very low at the end of the dry season. Excavated ponds usually are small (≤ 0.1 ha), and they cannot be drained at harvest.

The average depth of aquaculture ponds may range from 1 to 4 m, but most ponds have average depths of 1.25–2.0 m. Maximum depths of embankment and excavated ponds usually are not more than 0.5–1.0 m greater than average depth. Some watershed ponds may have maximum depths two to three times greater than average depths.

In extensive culture, ponds usually are fertilized and feed is not applied. Production typically is $< 0.5 \text{ t ha}^{-1} \text{ crop}^{-1}$. In semi-intensive culture, feeds are applied, but mechanical aeration is not used. Production usually is $1\text{--}2 \text{ t ha}^{-1} \text{ crop}^{-1}$. Both feeding and mechanical aeration are applied in intensive culture and production will typically be $> 3 \text{ t ha}^{-1} \text{ crop}^{-1}$. Extensive and semi-intensive ponds sometimes have areas in excess of 100 ha, but they usually are not greater than 10 ha in area. Ponds for intensive production seldom exceed 1 ha in water surface area and highly intensive culture ($> 20 \text{ Mt. ha}^{-1} \text{ crop}^{-1}$) is normally done in ponds with surface areas < 0.25 ha.

Water Use

Aquaculture farms often take large amounts of freshwater from streams or other water bodies. The amount of water required per tonne of aquaculture production varies with the type of water management used on a farm. Some farms use water only to fill ponds and maintain water levels, some use water exchange in which water is flushed through ponds daily, most pond aquaculture facilities drain ponds completely for harvest, while some retain pond water for reuse and only drain ponds at intervals of 5–10 years. Despite the method used, aquaculture farms discharge water, and they usually release it back into the same water body from which it was taken. Nevertheless, ponds reduce downstream flow, because of evaporation and seepage losses. There are cases where water use by aquaculture farms have reduced downstream flow causing conflicts with downstream water users. Also, when groundwater from wells is used in ponds, there can be competition for groundwater use.

Boyd (2005) suggested that water use in aquaculture be defined as the amount of reduction in downstream flow plus the removal of groundwater for use in ponds. This is similar to the way water consumption has traditionally been defined for irrigated agriculture, because irrigation water is from surface water bodies and groundwater sources (Wisser et al., 2008). In water footprint methodology in common use today, soil moisture replenished by precipitation and transpired by agricultural crops is called green water (Hoekstra and Mekonnen, 2012). Blue water is the term given to surface or groundwater used for irrigation of agricultural crops, and the volume of freshwater necessary to dilute the pollution from agricultural or other production process is termed gray water. This practice is used despite the fact that rain falling on terrestrial ecosystems evaporates whether land cover is crops, natural vegetation or other cover (Boyd and McNevin, 2015).

According to Verdegem and Bosma (2009) freshwater removal for aquaculture totals $16,900 \text{ m}^3 \text{ t}^{-1}$ production, but this estimate included green water and embodied water resulting from freshwater necessary to make feed ingredients. Tucker et al. (2017) estimated water use (including embodied water in feed) for channel catfish production in Mississippi as $2700 \text{ m}^3 \text{ t}^{-1}$. Boyd and McNevin (2015) calculated that $4088 \text{ m}^3 \text{ t}^{-1}$ were necessary to produce fish in ponds drained after each crop. Assuming that 46.2 Mt. of aquatic animals were produced in inland ponds in 2016, about 235 km^3 of freshwater would have been required. This quantity is larger than the storage volume of ponds which is around 165 km^3 based on pond area and average pond depth discussed previously. Additional freshwater was used in other inland aquaculture systems, but the volume was no doubt considerably less than that used in ponds.

In 2016, about 39.9 Mt. of aquaculture feed were produced (Alltech, 2017), and around 70% of the feed was used in inland, pond aquaculture. Chatvijitkul et al. (2017) found that embodied freshwater in feeds for freshwater species averaged $1370 \text{ m}^3 \text{ t feed}^{-1}$ and the land embodied in feed ingredient production was $0.239 \text{ ha t feed}^{-1}$. The use of embodied freshwater and land

in feed for freshwater aquaculture is therefore about 38.3 km³ and 6.7 Mha, respectively. Embodied freshwater accounts for only 16.2% of freshwater use in aquaculture production, and embodied land represents 28.3% of the total area devoted to inland farms.

Pond Management

The following is a list of the major management practices of which some or all may be applied in a particular type of pond aquaculture: ponds may be filled by rainwater and overland flow, or they are filled from streams, lakes, or wells; larger aquatic plants and animals are excluded by management practices; one or more selected species of fish or shrimp are stocked; fertilizers, liming materials, feed and other amendments are applied to promote production of the culture species; mechanical aeration may be applied; in the culture of some species, from 10% to 400% of the pond volume may be flushed from ponds by intentional input of water from the water source; some ponds have partial or complete plastic liners to avoid erosion of earthwork by aerator-generated water currents; ponds usually are drained to facilitate harvest and allow pond bottom soil treatments.

Aquaculture ponds receive inputs of nitrogen and phosphorus in organic fertilizers such as manures and other agricultural wastes, chemical fertilizers and feed. A low fertilizer application rate would be equivalent to around 0.25 kg nitrogen and 0.05 kg phosphorus ha⁻¹ day⁻¹, while some ponds may receive as much as 4 kg nitrogen and 1 kg phosphorus ha⁻¹ day⁻¹.

Usually 20–40% of nitrogen and phosphorus applied in fertilizers and feed to aquaculture ponds is recovered in fish at harvest (Boyd and Tucker, 1998; Boyd and Li, 2012). In crustacean farming, nitrogen recovery is similar, but only around 10% of phosphorus is recovered. Aquaculture feeds usually contain 4.5–7.0% nitrogen and 1.0–1.5% phosphorus (Chatvijitkul et al., 2018). At a daily input of 100 kg ha⁻¹ of a feed containing 5% N and 1% P and assuming 30% recovery of nitrogen and phosphorus in fish biomass at harvest, the daily nitrogen and phosphorus inputs to the water in feeding wastes would be about 3.5 kg N ha⁻¹ day⁻¹ and 0.7 kg P ha⁻¹ day⁻¹. Feeding rates in some ponds may be two to three times greater than in this example. Of course, ponds have a great ability to assimilate waste through microbial decomposition, ammonia diffusion, nitrification, denitrification, and phosphorus adsorption by sediment. No more than 10% of organic carbon and phosphorus and 30–40% of nitrogen added to ponds in feed and fertilizer are usually discharged in pond effluents (Boyd and Tucker, 1998).

High nutrient inputs make aquaculture ponds highly eutrophic. Typical rates of gross primary productivity range from 1 to 6 g carbon m⁻² day⁻¹ and values above 10 g C m⁻² day⁻¹ have been reported (Boyd and Tucker, 1998). Dense plankton blooms suppress light penetration and aquatic macrophytes usually are not abundant in aquaculture ponds. Moreover, the primary producers consist mainly of cyanobacteria. Of course, a large zooplankton community also develops in ponds, and bottom soils contain an abundance of benthic animals. Several studies have documented benthic insects, annelids, bivalves, gastropods, in the benthic environments of aquaculture ponds (e.g., Correia et al., 2002; Martinez-Cordova et al., 1998; Riise and Roos, 1997). It is likely that these contribute in some way to the feeding of cultured shrimp and fish species in those ponds.

Environmental Impacts

While the physiochemical and biological principles that operate to determine water quality and biological productivity are the same in aquaculture ponds as in natural water bodies, the two types of aquatic environments are structurally and hydrologically much different. Moreover, in aquaculture ponds, physiochemical, and biological processes are subjected to a high degree of management. Fertilized ponds are analogous to fertilized pastures for livestock, and ponds receiving feed are analogous to livestock production where feeds are used. Highly intensive pond aquaculture are similar to concentrated animal production facilities (feed lots).

The amount of land devoted to aquaculture in an area, and the manner in which the ponds are superimposed into the landscape varies. In some aquaculture areas, there are huge expanses of farms with ponds located very close together, and the main feature of the landscape is aquaculture ponds (Fig. 3). There also are single aquaculture farms widely separated from others and imposed into various landscapes (Fig. 4).

One environmental complaint about aquaculture is that it may result in conversion of large areas into ponds or it may cause disruption of terrestrial habitats by fragmentation of other land uses. The most serious ecological damage occurs when wetlands are converted to ponds and large areas of ponds are installed on flood plains. Additionally, aquaculture has been blamed for much of the conversion of mangrove habitats. Aquaculture has been estimated to account for roughly 544,000 ha of mangrove conversion (Hamilton, 2013). However, the topic of land conversion by aquaculture and the consequences of the conversions are not as well researched in freshwater systems.

Intensification of aquaculture can lessen the area of land and water use for aquaculture per tonne of production. The amount of embodied freshwater and land in feed depends on the efficiency with which the feed is used. Feed use efficiency often is calculated as the weight of feed needed to produce a unit weight of live aquaculture biomass at harvest. This ratio is called the feed conversion efficiency (FCR) which ranges from 1.2 to 2.5 depending upon the culture species and the effectiveness of pond management. A typical FCR for most pond culture species is 1.5–1.7.

There is a large input of organic matter to pond bottoms from organic fertilizers, feeding wastes, and dead plankton resulting in organic matter accumulation in sediment. Boyd et al. (2010) measured organic matter accumulation rates in 233 aquaculture ponds at 25 locations in nine countries; the accumulation rates ranged from 28 to 333 g C m⁻² year⁻¹ with an average of 150 g C m⁻² year⁻¹. Global carbon burial in aquaculture ponds was estimated to be 16.6 Mt. year⁻¹. By comparison large

Fig. 3 An aquaculture pond dominated landscape. Courtesy of Google Images (<https://www.pexels.com/photo/aerial-aquaculture-buildings-canals-1467519/>).

Fig. 4 A small aquaculture pond on a small-holder farm in the ponds. reservoirs on the world's rivers are estimated to sequester $160 \text{ Mt. C year}^{-1}$. Carbon sequestration in ponds offset a portion of the carbon dioxide emissions of aquaculture production. However, aquaculture farms are not carbon dioxide emission neutral, and they also result in emissions of methane and nitrous oxide which also are greenhouse gases (Ma et al., 2018; Rutegwa et al., 2019).

As previously discussed, the fish and crustacean populations in aquaculture ponds consist mainly of the species stocked. Ponds may be in monoculture, but many ponds in Asian countries are in carp or other polycultures (e.g., Costa-Pierce et al., 1984). Outside of the culture species, biodiversity is usually low in ponds. Plankton blooms normally consist of phytoplankton and zooplankton like cladocerans, copepods, and rotifers (e.g., Burke et al., 1986). The composition of plankton communities stimulated by fertilization in aquaculture ponds often consists of dense blooms of cyanobacteria. These organisms excrete odorous compounds into the water that can be absorbed by the culture animal resulting in an off-flavor in fish flesh (Tucker, 2010). Off-flavor has been particularly troublesome to the United States channel catfish industry, and it also has been observed in other fish and crustacean species. Pond bottoms usually are disinfected by lime treatment after ponds are drained (Boyd and Tucker, 1998). Although, this kills many

of the benthic organisms, the benthic community quickly recovers and aquaculture pond bottoms contain an abundance of annelids, chironomid larvae, and other worms (e.g., Tidwell et al., 1997). It has been suggested that benthic invertebrates play a role in nutrient cycling in aquaculture ponds (Adamek and Marsalek, 2013) and therefore may be important, even if they are often not considered so during production. In coastal areas in Southeast Asia, low intensity systems sometimes referred to as “silvo-fisheries” or “integrated mangrove aquaculture” exist where mangrove trees are grown in the ponds (Clough et al., 2002). These systems are primarily used for growing Black tiger shrimp (*Penaeus monodon*) and increase mangrove cover, however farmers typically allow some more valuable species like mud crabs (Family Portunidae) and milkfish (Family Chanidae) to remain in the ponds when the water is exchanged with the tidal flow. These wild fish and crustaceans are subsequently harvested with the shrimp periodically (Joffre et al., 2015), and therefore the practice is extractive from the local fish communities.

Because of the eutrophic nature of most aquaculture ponds, water discharged from ponds usually has higher concentrations of suspended solids and nutrients such as nitrate, ammonia nitrogen, and phosphate than found in receiving waters (Sarà, 2007a; Tucker and Hargreaves, 2008). Pond effluents also may have elevated bacterial abundance and contain aquatic animal pathogens (Sarà, 2007b). If many ponds discharge into the same water body, it can have a negative additive effect on the receiving waterbody, spread disease, and decrease the water quality of water used for intake in ponds downstream. Additionally, some ponds introduce chemicals such as antibiotics into the environment during culturing which are discharged into the environment (Holmstrom et al., 2003; Rico et al., 2012; Binh et al., 2018).

Aquaculture can have negative impacts on fish assemblages and other aspects of biodiversity in local streams, although the degree of this impact depends on the nature and quality of the receiving waters. Local predators may also interact with aquaculture ponds. Pond managers go to great lengths to prevent piscivorous birds from preying in ponds by using techniques such as complex netting systems and acoustic deterrents (Bevan et al., 2002), as well as lethal control methods (Blackwell et al., 2000). While typically not thought of when discussing aquaculture on a global scale, small-scale aquaculture facilities are managed to produce fish for stocking into natural waters to restore native fish populations. Fish population restoration is most common in North America and Europe. Aquaculture for restoration efforts is such a small fraction of the total global production that the production is often not counted in global aquaculture statistics like the FAO FishStat database. The one exception is the rearing and stocking of salmonid juveniles in the Pacific Northwest, the North Atlantic and elsewhere.

Conclusion

Pond aquaculture is an important source of animal protein for human diets, especially in Asia where most of aquaculture production occurs. Aquaculture has become as important as capture fisheries in producing aquatic food animals, and most freshwater aquaculture is conducted in ponds. Their combined water surface area and water volume is great enough to make ponds a small but significant component of the freshwater biome. Ponds have caused conversion of terrestrial to freshwater habitat, but the biodiversity of aquaculture ponds is low and likely does not add to the local biodiversity in many locations. Moreover, pond effluents can cause water quality deterioration in water bodies into which they are discharged. With the continued growth of aquaculture, the minimization of the impacts caused by production will be important in protecting local biodiversity. Ultimately, this means aquaculture needs to become more resource efficient, and will likely depend on responsibly increasing intensification, and not relying on an increase in new pond area for production.

Abstract

The constantly increasing production and use of synthetic plastic materials are responsible for the global increase in plastic debris in freshwater environments. Microplastics (MPs) have been found in the water and sediments of lakes and rivers worldwide, with concentrations correlated with human population density. Wastewater treatment plants have been identified as one of the main point sources for MP release, including microbeads and clothing fibers. Synthetic polymers are identified by their chemical composition using Fourier Transform Infrared and Raman spectroscopies. In freshwaters, the primary synthetic polymers that have been detected are polyethylene, polypropylene, polyester, and polystyrene. Field studies show that MPs are ingested by a variety of freshwater organisms, including clams, insects, and fish, but are retained at relatively low densities. Laboratory experiments document the effects that MPs can have on the metabolism, growth, survival, and reproduction of aquatic organisms, but usually at plastic particle concentrations that are orders of magnitude higher than those currently found in nature. The increased surface area of the small MP particles allows them to concentrate persistent organics pollutants from the aquatic environment. At this time there is limited information available on the concentration of toxic chemicals on freshwater MPs or the kinetics of the release of these compounds to organisms upon ingestion. Because MPs do not readily degrade, it is important for humans to reduce our reliance on plastic materials before their concentration in freshwater biomes reaches critical levels.

Introduction

The extensive use of plastic items worldwide can be attributed to plastics' flexible properties and low costs of production. For example, the physical characteristics of polyethylene and polypropylene give plastic items high resistance to aging and prevent deterioration (Derraik, 2002). Worldwide, plastic production has increased dramatically since the 1950s, reaching the current rate of 359 million metric tons per year (Plastics Europe, 2019). The cumulative production of plastic from 1950 to date has been calculated as over 8300 million metric tons (Blair et al., 2019). This excess production and use of plastic items have resulted in the designation of this era as the *Plasticene Age* or *Age of Plastics* (Reed, 2015). The production of plastic materials is expected to double in the next 20 years. With less than 25% of plastic items being recycled (Alimi et al., 2018), the potential for environmental pollution by plastic debris is intensifying. The fact that most plastics are not biodegradable on any reasonable human time scale increases the threat of environmental impact from plastic. Although plastics can photodegrade (UV-B degradation) and be broken down by mechanical abrasion, these processes end up producing massive amounts of small particles of microplastics (MPs) that continue to persist in the environment. An estimated eight million tons of plastic debris enters the oceans every year (Jambeck et al., 2015), but there is currently little information on the total amount of plastic accumulating in freshwater biomes.

MPs are small particles of synthetic polymers derived from petroleum and are produced intentionally (e.g. preproduction pellets) and unintentionally (e.g. fragmentation of larger plastic debris). MPs are a relatively new type of environmental contaminant whose impacts on ecosystems are very poorly understood. While MPs have received substantial attention in the marine environment, in freshwater biomes these particles have only been documented and studied during the last decade. MP particles have now been reported from freshwaters worldwide and an increasing number of studies are being conducted to explore the adverse effects that MP may have on aquatic organisms and ultimately on human health.

MPs are ubiquitous anthropogenic stressors affecting all of the world's biomes. MPs are found in the air (Panko et al., 2013; Sommer et al., 2018), water, and soil, and can easily be ingested by organisms (Browne et al., 2011). Due to their small sizes, MPs

can concentrate toxic compounds from the environment (Rodrigues et al., 2019). Additionally, some of the chemical additives used during plastic production are endocrine disruptors (Monneret, 2017). There is concern that MPs may also affect humans through ingestion, inhalation, or dermal contact (Prata et al., 2019b).

Classification and Types of MPs

Currently, there is no consensus on the definition of MPs based on size that is congruent with SI (System International) units. To distinguish macro and micro plastic particles, 5 mm was proposed as the maximum size limit for MPs (Arthur et al., 2009; Barnes et al., 2009; Ryan et al., 2009; Thompson et al., 2009). However, some researchers have used different size classifications for macro (1–100 cm), meso (1–25 mm), micro (1–5000 µm) and nanoplastics (1–100 nm or 1–20 µm) (e.g. Hartmann et al., 2019). Frias and Nash (2019) recently defined MPs as “any synthetic solid particle or polymeric matrix, with regular or irregular shape and with size ranging from 1 µm to 5 mm in maximum dimension, of either primary or secondary manufacturing origin, which are insoluble in water.” Whereas, the Group of Experts on the Scientific Aspects of Marine Environmental Protection (GESAMP, 2015) has noted the lack of international agreement on MP definitions, they currently recommend the use of MPs for all particles <5 mm in diameter. For this paper, we are only including reports of MP particles ranging from 1 to 5000 µm.

There are more than 5000 types of commercial plastic polymers (Wagner and Lambert, 2018), however, six polymers make up approximately 80% of plastic production: polypropylene (PP), polyethylene (PE), polyvinyl chloride (PVC), polyethylene terephthalate (PET, also known as polyester PES), polystyrene (PS), and polyurethane (PU), Table 1 (Utracki, 2003; Plastics Europe, 2019). Plastics with a density less than 1.0 g mL⁻¹ will float in freshwaters, while those with higher densities tend to sink (Andrady, 2011).

MPs are found in a variety of shapes in aquatic biomes including filaments/fibers, films, fragments, spheres/pellets and foams and occur in a range of colors including clear, white, red, brown, yellow, green, blue and black (Rodríguez-Seijo and Pereira, 2017). MP fibers are increasingly reported as one of the most common forms of MPs in samples from freshwater environments (Eerkes-Medrano and Thompson, 2018). Figs. 1 and 2 are showing MPs found in samples from environmental and cosmetic products.

MP Sources

MPs can be produced in two distinct ways. Primary MPs are plastic particles that are initially manufactured in small sizes, including virgin resin pellets or flakes and preproduction plastics. Synthetic microbeads are used in personal care products (facial cleansers,

Table 1 Some main types of plastics and their uses.

Name	Abbreviation	Density (g mL ⁻¹) ^a	Uses
<i>Thermoplastics</i>			
Polypropylene	PP	0.90	Food packing, snack wrappers, automotive parts, bank notes
High density polyethylene	HDPE	0.96	Toys, milk bottles, shampoo bottles, houseware, pipes
Low density polyethylene	LDPE	0.92	Bags, trays, containers, agricultural films
Polyvinyl chloride	PVC	1.40	Windows frames, floor and wall covering, pipes, cables
Polyethylene terephthalate ^b	PET/PETE/PEST	1.55	Soda and water bottles, clothing
Polystyrene	PS/PST	<1.05	Expanded foam, eyeglasses frames, egg trays, insulation, cups
Polyamides (nylons)	PA	1.02–1.14	Adhesives, fibers, films, clothing
Polycarbonate	PC	1.36	Electrical connectors, insulators, medical tubing, instrument covers
Polymethylmethacrylate	PMMA	1.18	Lightweight sheets or Plexiglass™
<i>Thermosets</i>			
Polyurethane	PU/PUR	1.052	Building insulation, pillows and mattresses, fridge insulations
Epoxy resins	EP	1.82	Adhesives, glass reinforced, paints and coatings
Polyvinyl ester	PVE	1.80	Paints, transportation, buildings, aerospace,
Cellulose acetate	CA	1.30	Containers, tools, packaging, fibers
Silicone		1.5	Seals, O-rings, linings, insulations
Phenol formaldehyde	PF	1.21	Bakelite™, billiard balls, paints, plywood
Urea formaldehyde	UF	1.5	Decorative laminates, textiles, cotton blends, electrical appliances
Phenolic resins	PH	1.28	Laboratory countertops, coating, adhesives, billiard balls
Acrylic resins	AC	1.19	Automotive, architectural, coating

^aSea water density 1.02–1.03 g mL⁻¹, freshwater density ~1.0 g mL⁻¹.

^bPolyethylene terephthalate is also known as polyester (PES).

tooth pastes, shower gels, makeup, insect repellents and sunscreens) and as carriers for certain types of medicine. They occur in powders used for injection molding and in ink for 3D printers. Primary MPs are frequently used as industrial abrasives for cleaning using air/water-blasting, and are found in drilling fluids employed in oil and gas exploration (Duis and Coors, 2016).

Secondary MPs are produced by fragmentation of larger plastic items as a result of photodegradation (UV radiation) and physical abrasion which produce small particles that fall into the micro- or even nanoparticle size ranges. Sources of MP fragments include the breakdown of plastic bags, bottles, cups, food wraps, plastic films used to cover agricultural soil and crops, foam insulation materials, and even from automobile tires (Duis and Coors, 2016; Wagner and Lambert, 2018). Synthetic microfibers are created from degradation of clothing and textile products containing blends of polyester, polyacrylic, and nylon (Browne et al., 2011).

Plastic materials can enter aquatic systems from accidental industrial spills, runoff from agricultural fields that use plastic mulches, inadequate recycling, discharges from municipal wastewater treatment plants, and individual littering. Microbeads that are used in cosmetics and toothpastes often end up in domestic wastewater. Kalčíková et al. (2017) reported the daily release of an average of 15.2 mg of microbeads per person to the sewage system in Ljubljana, Slovenia. MP fibers produced from laundering textiles are another major source of MP pollution. Washing a normal 6 kg load of polyester-cotton blend clothing can release 138,000 fibers, while 496,000 fibers can be produced from a load of polyester clothing, and 729,000 fibers from a load of acrylic materials (Napper and Thompson, 2016). The initial washing of fabrics releases the largest amount of fibers, but fibers continue to be released even after ten washings (De Falco et al., 2019).

While there are many sources of MPs in freshwater systems, wastewater treatment plants (WWTPs) are one of the most important point sources for microfibers and microbeads (Carr et al., 2016; Dris et al., 2018; Ou and Zang, 2018). WWTPs were developed with the objective of treating human and industrial wastes to remove organic matter, nutrients, and harmful bacteria so that treated effluents could be discharged into marine and freshwater systems without compromising human health or causing environmental

damage (Vijayan and Mohan, 2013). The plants are not specifically designed to remove MPs and during treatment can actually form additional MP sized particles when larger particles are abraded as the plastic debris moves through the plant.

Studies have examined the effectiveness of plants with primary, secondary, and tertiary treatment methods in removing MPs (Table 2). Influent waters often contain between 12 and 7000 plastic particles (pp) L⁻¹ (Gündoğdu et al., 2018; Simon et al., 2018). Tertiary WWTPs are able to remove up to 98% of the microliter (natural and synthetic) during treatment which includes screening, grit removal, and chemically enhanced settling (Talvitie et al., 2017). Smaller MP fragments as well as natural (cotton, linen and wool) and synthetic textile fibers may pass through the screens used for sewage treatment. Michielssen et al. (2016) reported that fibers were the predominant form of microliter released from WWTPs and could account for 80% of the material in the final effluent. Confirmation of the composition of the fibers is important when determining the amount of MP material actually discharged to the environment (Ziajahromi et al., 2017b). Talvitie et al. (2017) found that up to 66% of the textile fibers that were released in treated effluent samples were natural and not synthetic.

While effectively treated effluents from WWTP can contain very low concentrations of MPs (0.3×10^{-6} pp L⁻¹ (Carr et al., 2016), due to the large volumes of water treated, this can still result in the release of several thousand MP particles to the aquatic environment each day. A WWTP in Detroit, MI (USA) was estimated to discharge approximately 9 billion fibers (natural and synthetic) per day in its effluent, representing the release of 3800 fibers per person per day into the Detroit River (Michielssen et al., 2016). Improved treatment plant designs can reduce this discharge load.

MP fragments and fibers that are retained by the WWTPs usually end up in the sewage sludge. Mahon et al. (2017) found that sludge contained 4200–15,400 MP particles kg⁻¹ dry weight. The most common form of MP found in the sludge was fibers (Mahon et al., 2017; Talvitie et al., 2017). Treated sludge, known as biosolids, is often applied to farmland as fertilizers. In the United Kingdom, approximately 80% of sewage sludge is applied to agricultural soils (Horton et al., 2017). Runoff from the fields can resuspend the fibers and transport them to rivers and lakes, or to the ocean.

MP Collection and Identification

MP particles have been found in freshwater ecosystems throughout the world, floating at the water's surface, suspended in the water column, intermixed with beach and bottom sediments, and even in the digestive tracts of aquatic organisms. The methods used to collect MPs in freshwaters are similar to those used in marine environments (Wang and Wang, 2018). MPs can be collected from the water using nets, trawls, pumps and grab samples. The mesh that is used to collect and concentrate the samples varies considerably (20–500 µm), with smaller meshes clogging faster, but retaining smaller sized MPs. Metallic grabs or corers are used to collect samples of bottom sediments, while the top five cm of beach sediments are generally collected by hand and sieved. A variety of techniques are used to collect biota, depending on the study design. The distribution of MPs in freshwaters has not been documented as well as that of marine ecosystems. The diverse hydrological patterns of inland lakes and rivers that receive runoff from urban and agricultural areas leads to large variations in MP concentrations within the water bodies and requires a large number of samples to adequately describe the distribution pattern of the particles (Horton et al., 2018).

MP particles must be sorted from the other material in the water or sediment samples prior to enumeration and identification. Some researchers use density separation, which involves adding solutions with a high specific gravity (ZnCl₂, NaCl, NaBr, NaI, CaCl₂, ZnBr₂, or Na₂WO₄) to the sample and then collecting the MPs that float to the top of the sample. Samples are often sieved to isolate materials of different sizes for analysis. If a lot of plankton is present in the samples, chemicals (KOH, H₂O₂, Fe²⁺, acids, and enzymes) may be added to digest the organic matter. MPs are then examined qualitatively or quantitatively (Fig. 3). Qualitative analyses involve visually or microscopically sorting and counting particles that resemble plastic materials, while qualitative analyses include additional steps to confirm the identity of the plastic polymers. Microscopy generally cannot differentiate MP particles less than 50 µm (Alam et al., 2019) and it is critical to use quantitative techniques to avoid counting paint chips, natural cellulose fibers or fly ash as MPs (Eriksen et al., 2013). On the other hand, due the large numbers of particles in samples, fluorescent dyes (Maes et al., 2017) and Nile Red (Andrady, 2011) are being used during sorting in qualitative analyses to rapidly distinguish the stained MPs from the background material. However, some synthetic polymers do not stain and this can affect the identification and quantification of MP particles and fibers (Prata et al., 2019a).

Hyper-Spectral Imaging (HSI) in the Short-Wave Infrared (SWIR) range is another technique used to detect plastic by differentiation of absorption bands in the spectra region and vibration of C–H molecular bonds. Serranti et al. (2018) found that this technique can identify plastic debris floating in the ocean (PP, PE and PS) in a size range of 1–5 mm. Elemental analysis using Scanning Electron Microscopy with energy dispersive X-ray spectroscopy (SED/EDX) has been used to differentiate particles with high organic content from plastic (Girão et al., 2016; Wagner et al., 2017).

In order to advance MP research, the correct identification of MP particles is essential and Fourier Transform Infrared (FTIR) and Raman spectroscopies are the main quantitative techniques used to identify synthetic polymers of plastics. These vibration spectroscopy techniques detect the chemical bonds in the samples and can differentiate between the different types of synthetic polymers and natural debris. These instruments use their own libraries to identify the polymers. Micro-FTIR with Attenuated Total Reflection (ATR) and micro-Raman can analyze particles as small as 5–10 µm (Käppler et al., 2016). Pyrolysis-gas chromatography-mass spectrometry (Pyr-GC-MS) is another technique used to obtain information about plastic polymers. This technique is based on thermal degradation and pyrolysis of polymer fragments which are separated by GC and characterized by MS (Mintenig et al., 2018). Thermal extraction desorption gas chromatography mass spectrometry (TED-GC-MS) permits the identification of MPs without requiring any sample treatment (Dümichen et al., 2017).

Fig. 3 Analytical techniques to identify MPs in freshwater environmental samples.

Distribution of MPs in Freshwaters

The number of reports of MPs from freshwater lakes and rivers has increased dramatically from 2012 through 2019 (Table 3). Research has been concentrated in Europe, Asia, and North America, but studies of the inland waters of Africa, South America, and Australia have begun in the last few years. The data from various authors is not directly comparable due to the use of different collection and processing methods and a lack of standardization of reporting units (Rios Mendoza and Balcer, 2019a). MP concentrations in surface waters ranged from 0–270 pp L⁻¹ by volume and 0–563 pp m⁻² by surface area. In bottom sediments the concentrations range from 0–10 pp g⁻¹ sediment, while on beaches densities varied from 0–0.8 pp g⁻¹ or 0–2117 pp m⁻² (Table 3).

In spite of the lack of harmonization of sampling techniques, certain trends are evident. China has the highest plastic production in the world (Plastics Europe, 2019), including textiles, and makes extensive use of plastic films as mulch for agricultural use (Lv et al., 2019; Wang et al., 2019b). Surface waters of lakes and rivers in China contain some of the highest MP concentrations, often over 1000 pp m⁻³ (Table 3). Worldwide, urban areas generally contain higher concentrations of MPs than rural areas (Table 3), and stormwater retention ponds tend to concentrate MPs, with levels reaching 23–270 pp L⁻¹ in water and 9.5×10^5 pp kg⁻¹ dw sediment (Liu et al., 2019; Olesen et al., 2019).

With regards to MP morphology, the most common forms were fibers > fragments > pellets or microbeads. The presence of sewage plants increases the concentration of MPs in the water, especially of fibers (Browne et al., 2011; McCormick et al., 2014; Wang et al., 2017a, b).

MPs and Toxic Compounds

MPs contain a mixture of chemicals that are introduced during their manufacture, including additives, stabilizers, flame-retardants, antibacterial and antioxidant agents, pigments, fillers, and plasticizers including phthalates (Hahladakis et al., 2018). These chemicals can be released when MPs enter aquatic environments, leading to the suggestion that plastic be classified as a hazardous material (Rochman et al., 2013a). While information on the interaction of toxic compounds with MPs in freshwater systems is limited at this time, it is an important factor in understanding the adverse effects of environmental pollution on aquatic organisms.

Macro, micro and nanoplastic debris can concentrate and transport toxic compounds in the environment (Mato et al., 2001; Rios et al., 2007) and assessing the abundance of the MP particles and measuring their sizes is essential to determining the real risk of these plastic particles. Smaller particles (Fig. 2) have larger surface areas and can concentrate higher amounts of toxic compounds on their surfaces. MPs adsorb persistent organic pollutants (POPs), semipersistent polycyclic aromatic hydrocarbons (PAHs), heavy metals and pharmaceutical chemicals from the aquatic environment.

The main mechanisms for chemical adsorption on plastics are through hydrophobic (Wang et al., 2019a; Guo and Wang, 2019), electrostatic (Guo and Wang, 2019), van der Waals (Xu et al., 2018), or double bonds interactions (Hüffer and Hofmann, 2016). Rios and collaborators have studied the toxic compounds adsorbed on the surfaces of MPs collected from the Laurentian Great Lakes. They detected PAH concentrations ranging from 0.47–20.26 µg g⁻¹ on MPs from the Great Lakes and from the St Louis River Estuary (SLRE). PCBs ranged from nondetectable to 9.86 µg g⁻¹ in samples from the Great Lakes and from 0.40–3.46 ng g⁻¹ in SLRE. Organochlorine pesticide concentrations varied from 4.3–63.9 ng g⁻¹ (Rios Mendoza and Balcer, 2019b; Rios Mendoza, 2019). Faure et al. (2015) reported toxic compounds on MPs from Swiss Lakes with PAHs ranging from 0.086–5.714 µg g⁻¹, PCBs from 0.4–548 ng g⁻¹, and organochlorine pesticides from 1.4–2715 ng g⁻¹.

Interactions of Aquatic Organisms with MPs

MPs as a Habitat for Microbes

Plastic debris can be colonized by a variety of microbes and develop into a unique aquatic community known as the “plastisphere” (Zettler et al., 2013). These diverse floating colonies can be transported long distances across the water surface. As the biofilm grows and increases in density, the plastic material and its associated microbial community can sink, thus serving as a vector for the spread of potentially harmful bacteria and other organisms throughout the water column (McCormick et al., 2014).

McCormick et al. (2014) found that microplastic pellets and fragments collected near a WWTP in the North Shore Channel of Chicago IL developed an extensive biofilm of prokaryotic organisms with a density up to $0.3 \text{ cells } \mu\text{m}^{-2}$ of surface area. DNA sequencing revealed that the bacterial community on the MP particles was distinct from that of the water column or on natural

organic material from the same area and contained a high abundance of *Pseudomonas*, which may be able to degrade MPs. Several genera of bacteria that contain pathogenic strains were also found at elevated levels on MP particles (McCormick et al., 2014).

By serving as a substrate, MPs enable bacteria to grow in close contact with each other, potentially allowing for increased horizontal gene transfer (HGT) or exchange of genetic information via plasmid transfer. This exchange could lead to the formation of more antibiotic resistant strains of bacteria. Arias-Andres et al. (2018) studied this hypothesis using a strain of *Escherichia coli* with a plasmid that encodes for trimethoprim resistance. They found a large increase in the HGT rate in bacteria grown in water from Lake Stechlin, Germany that contained microplastic particles versus controls without microplastic.

Field Studies on Ingestion and Other Interactions

MP particles that enter freshwater environments may be consumed by a variety of aquatic organisms including clams, worms, crayfish, insects, tadpoles, and fish (Table 4). The ability to detect small MPs in aquatic organisms is affected by the analytical procedures that are used to extract and identify the possible MP particles. Some researchers dissected the digestive tracts and examined the contents microscopically, while others chemically dissolved the digestive tract or the entire organism to remove organic material and then separated the MP particles by flotation or filtration prior to microscopic examination.

Recent studies have included the use of FTIR spectroscopy to confirm that the microparticles are actually MPs and not other natural materials such as cellulose, cotton, wood, or sand grains. The most commonly ingested form of MPs was fibers comprised of PES, PE/PET, PE, and PP (Table 4). The percentage of examined organisms that contained MPs varied considerably (Table 4), ranging from 20% or less (Sanchez et al., 2014; Faure et al., 2015; Phillips and Bonner, 2015; Biginagwa et al., 2016; Roch and Brinker, 2017; Roch et al., 2019; Su et al., 2019) to over 75% (Jabeen et al., 2017; Silva-Cavalcanti et al., 2017; Campbell et al., 2017; Nel et al., 2018; Xiong et al., 2018). While MP particles were commonly found in aquatic organisms, the density of MP per individual was generally quite low (<3 pp ind⁻¹, Table 4). Higher densities of MPs were found in bottom feeding fish and those from urban locations with more environmental contamination (Zheng et al., 2019; Silva-Cavalcanti et al., 2017; Peters and Bratton, 2016; Sanchez et al., 2014; Phillips and Bonner, 2015).

While field studies have concentrated on determining the number of MPs ingested by aquatic animals, organisms can interact with plastic debris in other ways. Caddisfly larvae build external cases or tubes from sand and other materials that they find in the environment (Fig. 4) and can incorporate MPs if they are present. MP particles were found in 7% of the cases of caddisfly larva collected from an urban section of the River Tame, United Kingdom (Tibbetts et al., 2018) and in 58% of the cases of the species *Lepidostoma basale* from a stream in Germany (Ehlers et al., 2019).

Laboratory Studies

Several laboratory experiments have investigated the interactions of MPs with aquatic organisms ranging from microbes to fish under more controlled conditions (Table 5). Organisms have been exposed to MPs via water, sediment, or through their diets. The test concentrations of MPs have been reported using a variety of units, including number or weight of plastic particles per unit weight of sediment, or per volume of test medium. Due to the wide variation in size and weights of the MP particles, some authors have begun to report test concentrations both by weight and number of particles. Experimental exposures of MP concentrations have ranged from 0.5–2570 pp g⁻¹ or 2–20 mg g⁻¹ dry weight in sediment, and from 50– 1×10^{10} pp L⁻¹ or 0.01– 1×10^4 mg L⁻¹ in water. The most commonly tested forms of MP have been PE and PS spheres and fragments and PES/PET fibers (Table 5).

Initial studies were designed to determine whether or not MPs of various shapes and sizes could be ingested and to what degree the particles would accumulate in the guts of the test organisms (Imhof et al., 2013; Rochman et al., 2017; Murphy and Quinn, 2018; Li et al., 2019; Cuthbert et al., 2019). While plastic particles are readily ingested by a variety of organisms (Table 5), they are also egested fairly rapidly, resulting in a low body burden in most test organisms (<15 pp ind⁻¹, or <4.1 pp g⁻¹). Some size selectivity was observed, with *Gammarus* ingesting smaller MP fragments (32–63 μ m) at the highest rates (Straub et al., 2017; Weber et al., 2018). Li et al. (2019) found that the number of fibers ingested by Asian clams was related to the flexibility of the plastic polymer (Table 5), with PET fibers favored over PEA and AC. The more rigid PA, RA and PVA fibers were not ingested as readily.

Ingested MP materials can be retained in an organism's digestive tract or passed through the body to be egested in the feces. Smaller sized particles may move from the gut into other body tissues by crossing the epithelial lining. To determine the concentration of MP in various parts of an organism, researchers may dissect or dissolve the specific organs to extract and count the individual plastic particles. When exposing organisms to smaller particles, the practice has been to use MPs labeled with fluorescent dyes and then use imaging to detect the dye and particles in various locations in the organism. The strength of the fluorescent signal is correlated to the number of particles ingested. Organisms can be damaged during sample preparation (Guilhermino et al., 2018), allowing particles to appear in other tissues besides the gut. While MPs have primarily been found in the digestive tracts of organisms (Table 5), small MPs (1–5 μ m) have been reported from various tissues of Asian clams (Guilhermino et al., 2018), zebra mussels (Magni et al., 2018), *Daphnia* (Rosenkranz et al., 2009) and zebrafish (Lu et al., 2016). Schür et al. (2019) questioned the ability of fluorescent microbeads to move from the gut of *Daphnia* through the peritrophic membrane (which coats the food pellets in cladocerans), and then through the gut epithelium into lipid droplets. They found that fluorescent dyes can leach from plastic particles and end up in lipids, even when MP particles were not visible. Catarino et al. (2019)

^bMesoplastics ranged from 5.1 to 25 mm in length.

Data sources: See References.

Fig. 4 Limnephilidae caddisfly case with MPs added by authors to show sizes of natural debris with plastic particles.

also reported that the use of fluorescence alone is not sufficient to prove that MP particles have moved from the gut into other organs, especially for particles $>1\ \mu\text{m}$ in size.

MPs can affect aquatic organisms in a variety of ways. Canniff and Hoang (2018) found that algal growth increased in the presence of PE beads which may have served as a substrate for the algae. On the other hand, Lagarde et al. (2016) reported that algal growth was reduced after 78 days of exposure to PP and HDPE fragments, hypothesizing that algal colonization and aggregation of the MPs increased the density of the fragments which settled out of the water column.

Many scientists have employed standardized toxicity test methods to examine the effects of MP on amphipods, water fleas, and fish. These experiments exposed test organisms to a range of MP concentrations under controlled conditions and then determined the highest concentration that had no effect of the organisms (NOEC), the lowest concentration that initiated an observed effect (LOEC), and the concentrations that caused an effect or were lethal to 50% of the test organisms (EC50 and LC50 respectively). Effects can include reduced feeding rates, motility, growth, reproduction, or survival.

Redondo Hasselerharm et al. (2018) reported that only one of six benthic invertebrate species they tested were affected by MPs when exposed to PS fragments in sediments at concentrations up to 40% of the sediment dry weight (Table 5). The amphipod *Hyalella azteca* was more sensitive to PP fibers (10-day LC50 = $71\ \text{pp mL}^{-1}$) than to PE particles (10-day LC50 = $46,400\ \text{pp mL}^{-1}$, Au et al., 2015). Ziajahromi et al. (2018) found that growth and survival of the midge *Chironomus* was affected by MP at environmentally realistic concentrations ($0.5\ \text{pp g}^{-1}$) in sediments.

MP can interfere with some organisms' ability to swim or feed by becoming entangled in their appendages or filling their guts (Table 5). Eltemsah and Bøhn (2019) reported a 5-day EC50 mobility of $35\text{--}52\ \text{mg L}^{-1}$, for the waterflea, *Daphnia*, exposed to $6\ \mu\text{m}$ PE beads. PE fragments affected *Daphnia* reproduction more than PE beads (21-day EC50 = $8.6 \times 10^4\ \text{pp mL}^{-1}$ versus $2.8 \times 10^5\ \text{pp mL}^{-1}$, Ogonowski et al., 2016). *Ceriodaphnia* are more sensitive than *Daphnia* to MP pollution (Ziajahromi et al., 2017a) and showed greatest sensitivity to PES fibers than to other forms. Although the fibers were not ingested, they interfered with *Ceriodaphnia* swimming and led to a 48-h LC50 of $1.5\ \text{mg L}^{-1}$ or $1.3 \times 10^4\ \text{pp L}^{-1}$. In chronic 21-day tests, Jaikumar et al. (2019) found that MP concentrations as low as $100\ \text{pp mL}^{-1}$ decreased at least one component of reproduction in three species of water fleas.

More sensitive biological tests have been used to detect evidence of physiological effects (Table 5) including oxidative stress, neurotoxicity, and immune responses in model organisms including fish (Karami et al., 2016; Lu et al., 2016; Haghi and Banaee, 2017; Jin et al., 2018; Lei et al., 2018; Wen et al., 2017).

Adverse effects in the environment can be caused by exposure of organisms to MP particles themselves or to pollutants that have been absorbed by the MPs. Laboratory studies have been conducted to examine the combined effects of MPs and a variety of chemical contaminants (Table 6). Wardrop et al. (2016) and (Rochman et al., 2013b) fed fish a diet that contained MP particles that had been exposed to PBDE, PAHs, and PCBs in the environment. Bioaccumulation of the contaminants in the test organisms was enhanced for some of the congeners. In experiments where organisms were exposed to MP and chemical contaminants in the same test solution, the MPs often increased the uptake and toxicity of the chemicals (Guilhermino et al., 2018; Frydkjær et al., 2017; Karami et al., 2016; Haghi and Banaee, 2017) or the effects were additive (Ma et al., 2016).

Ziajahromi (2018) found that MPs may decrease the toxicity of insecticides to midge larvae in lab water, but did not see the same effect in river water where higher organic carbon levels may have had a greater affinity for the insecticide. Understanding the chemical partitioning rates between chemical contaminants and plastics versus natural organic carbon is critical for predicting the effects of MP on chemical transfer in aquatic ecosystems. Frydkjær et al. (2017) found that PE fragments absorbed phenanthrene at a rate 8–35 times lower than natural plankton under laboratory conditions and they concluded that since the abundance of plastic in aquatic environments is much less than that of plankton, plastic may not be significant route of enhanced chemical exposure to organisms in the food chain.

Zebra mussel <i>Dreissena polymorpha</i>	AC fibers PA fibers RA fibers PVA fibers PET fibers PET fibers 100–250 PET fibers 1000–5000 PS beads 1 and 10	100 and 1000 pp L ⁻¹ 100 and 1000 pp L ⁻¹ 100 and 1000 pp L ⁻¹ 100 and 1000 pp L ⁻¹ 100 and 1000 pp L ⁻¹ 100 and 1000 pp L ⁻¹ 100 and 1000 pp L ⁻¹ 5 $\times$ 10 ⁵ pp L ⁻¹ of each size and 2 $\times$ 10 ⁶ pp L ⁻¹ of each size	MP found in gut lumen, tissues, and hemolymph. Increased level of dopamine, did not produce oxidative stress or genetic damage.	Magni et al. (2018)
Mud snail <i>Potamopyrgus antipodarium</i>	Polymethyl methacrylate fragments 29.5	1:10 ratio of plastic to food	MP ingested, 87.8% of feces contained MPs	Imhof et al. (2013)
European fingernail clam <i>Sphaerium corneum</i>	PS fragments 20–500	0.1–40% of sediment dw	NEF survival or growth in 28 days	Redondo Hasselerharm et al. (2018)

<i>Annelida</i> <i>Lumbriculus variegatus</i>	Polymethyl methacrylate fragments 29.5	1:10 ratio of plastic to food	93% ingested MPs	Imhof et al. (2013)
	PS fragments 20–500	0.1–40% of sediment dw	NEF growth or reproduction in 28 days	Redondo Hasselerharm et al. (2018)
<i>Tubifex</i> spp.	PS fragments 20–500	0.1–40% of sediment dw	NEF survival or growth in 28 days	Redondo Hasselerharm et al. (2018)
<i>Nematoda</i> <i>Caenorhabditis elegans</i>	PA fragments 70	0.5–10.0 mg m ⁻²	Decreased survival, growth, reproduction, and intestinal calcium levels. Oxidative stress noted. LOEC = 0.5 mg m ⁻²	Lei et al. (2018)
	PE fragments 70	0.5–10.0 mg m ⁻²	Decreased survival, growth, reproduction, and intestinal calcium levels. Oxidative stress noted. LOEC = 0.5 mg m ⁻²	
	PP fragments 70	0.5–10.0 mg m ⁻²	Decreased survival, growth, reproduction, and intestinal calcium levels. Oxidative stress noted. LOEC = 0.5 mg m ⁻²	
	PVC fragments 70	0.5–10.0 mg m ⁻²	Decreased survival, growth, reproduction, and intestinal calcium levels. Oxidative stress noted. LOEC = 1.0 mg m ⁻²	
	PS spheres 0.1, 1.0, 5.0	0.5–10.0 mg m ⁻²	PP accumulated in digestive system. Caused oxidative stress, decreased survival, growth, reproduction, and intestinal calcium levels. 1.0 µm particles most lethal. LOEC = 0.5 mg m ⁻²	
<i>Crustaceans</i> Ostracod <i>Notodromas monacha</i>	Polymethyl methacrylate fragments 29.5	1:1 ratio of plastic to food	32.4% ingested MPs	Imhof et al. (2013)
Isopod <i>Asellus aquaticus</i>	PS fragments 20–500	0.1–40% of sediment dw	NEF survival or growth in 28 days	Redondo Hasselerharm et al. (2018)
Amphipod <i>Gammarus duebeni</i>	PE spheres 10–45	Fed <i>Lemna minor</i> with adsorbed MP	29% contained pp after 24 h depuration period, NEF survival in 48 h exposure	Mateos-Cárdenas et al. (2019)
Amphipod <i>Gammarus fossarum</i>	PA fibers 500 × 20	100–1.3 × 10 ⁴ fibers cm ⁻² basal area of chamber	Ingested and egested rapidly. NEF feeding rate. Decreased assimilation efficiency at 2680 fibers cm ⁻²	Blarer and Burkhardt-Holm (2016)
	PS beads 1.6	500–6 × 10 ⁴ pp mL ⁻¹	PP ingested, found in gut but not in midgut glands or epithelial cells of gut. NEF feeding rate or assimilation efficiency at 12,500 beads mL ⁻¹	Straub et al. (2017)
	PHB fragments (biodegradable) 32–250	10–1 × 10 ⁵ pp ind ⁻¹	32–63 µm particles ingested in highest amounts, NEF feeding rate or assimilation efficiency. Decreased weight gain	
Amphipod <i>Gammarus pulex</i>	PMMA fragments 32–250	10–1 × 10 ⁵ pp ind ⁻¹	32–63 µm particles ingested in highest amounts, decreased assimilation efficiency and weight gain	Imhof et al. (2013)
	Polymethyl methacrylate 29.5	1:10 ratio of plastic to food	Ingested, 96% of feces contained MPs	
	PS fragments 20–500	0.1–40% of sediment dw	16–165 µm MPs were ingested. Ingestion rate proportional to sediment dose. NEF survival or feeding rate in 28 days. EC10 growth = 1.07% EC50 growth = 3.57%	Redondo Hasselerharm et al. (2018)

Table 5 (Continued)

Organism	Exposure conditions		Results	References
	Particle type and size (μm)	Plastic concentration		
Amphipod <i>Hyalella azteca</i>	PET fragments 10–150	0.4–4000 pp mL ⁻¹	High ingestion of fragments <53 μm , up to 6600 pp ind ⁻¹ NEF survival, metabolism or feeding in 48 days	Weber et al. (2018)
	PE particles 10–27	10 - 1 $\times$ 10 ⁵ pp mL ⁻¹ acute exposure 5 $\times$ 10 ³ – 2 $\times$ 10 ⁴ pp mL ⁻¹ chronic exposure	MP ingested, but did not translocate out of gut. NEF growth in acute exposure. Decreased reproduction and growth in chronic exposure. 10-day LC50 = 46,400 pp mL ⁻¹	Au et al. (2015)
	PP fibers diameter 20 length 20–75	22.5–90 pp mL ⁻¹	MP ingested, but did not translocate out of gut. Increased egestion time. Decreased growth. 10-day LC50 = 71.43 pp mL ⁻¹	
	PS fragments 20–500	0.1–40% of sediment dw	No MP ingestion. NEF survival, feeding rate or growth in 28 days.	Redondo Hasselerharm et al. (2018)
Water flea <i>Ceriodaphnia dubia</i>	PE beads 1–4	0.5–16 mg L ⁻¹ $\approx$ 1.7 $\times$ 10 ⁴ –5.4 $\times$ 10 ⁵ pp L ⁻¹	Beads ingested, gut full at 4 mg L ⁻¹ and higher 48-h LC50 = 2.2 mg L ⁻¹ (7.4 $\times$ 10 ⁴ pp L ⁻¹)	Ziajahromi et al. (2017a)
	PE beads 1–4	62.5–2000 μg L ⁻¹ $\approx$ 2.1 $\times$ 10 ³ –6.7 $\times$ 10 ⁴ pp L ⁻¹	8-day EC50 reproduction = 958 μg L ⁻¹ (3.2 $\times$ 10 ³ pp L ⁻¹)	
	PES fibers 26–1150 long average 280	0.125–4 mg L ⁻¹ $\approx$ 1.1 $\times$ 10 ³ –3.4 $\times$ 10 ⁴ pp L ⁻¹	No fibers ingested, but bubbles noted under carapace, antennal and carapace deformities, fibers affected swimming behavior 48-h LC50 = 1.5 mg L ⁻¹ (1.3 $\times$ 10 ³ pp L ⁻¹)	
	PES fibers 26–1150 long average 280	31.25–1000 μg L ⁻¹ $\approx$ 272–8600 pp L ⁻¹	8-day EC50 reproduction = 429 μg L ⁻¹ (3.5 $\times$ 10 ³ pp L)	
Water flea <i>Daphnia magna</i>	PE spheres 1–5	1 $\times$ 10 ³ –1 $\times$ 10 ⁷ pp mL ⁻¹	18 °C 96-h NOEC = 5.0 $\times$ 10 ³ pp mL ⁻¹ Little change at higher temperatures	Jaikumar et al. (2018)
	PE fragments 1–10	1 $\times$ 10 ³ –1 $\times$ 10 ⁷ pp mL ⁻¹	18 °C 96-h NOEC = 1.0 $\times$ 10 ⁵ pp mL ⁻¹ Little change at higher temperatures	
	PE spheres 1–5	100–1 $\times$ 10 ⁵ pp mL ⁻¹	21-day LOEC reproduction = 100 pp mL ⁻¹	Jaikumar et al. (2019)
	PE fragments 1–10	100–1 $\times$ 10 ⁵ pp mL ⁻¹	21-day LOEC reproduction = 100 pp mL ⁻¹	
	Fluorescent PS beads 0.02 and 1.00	2 μg L ⁻¹	Both sizes ingested. Fluorescence appeared in gut and lipid storage droplets. Depuration rate faster for the larger MP beads	Rosenkranz et al. (2009)
	PMA fragments 29.5	1:10 ratio of plastic to food	100% ingested MP	Imhof et al. (2013)
	PET fibers 60–1400 long, 30–530 wide, 2–21.5 thick	12.5–100 mg L ⁻¹ $\approx$ 6.64 $\times$ 10 ⁴ –5.3 $\times$ 10 ⁵ fibers L ⁻¹	MP uptake and depuration noted, increased mortality in 48 h in unfed organisms- not dose dependent.	Jemec et al. (2016)
	PS 0.05–10	1–50 mg L ⁻¹	Uptake and depuration of MP and NP observed. NEF from larger particles. 0.05 μm NP most toxic. 48-h EC50 immobilization = 15.13 mg L ⁻¹ , damaged swimming/feeding appendages.	Ma et al. (2016)
	PE beads 4.1 $\pm$ 1.0	100–2.25 $\times$ 10 ⁵ pp mL ⁻¹	Decreased feeding rate, and growth, increased mortality. 21-day EC50 reproduction = 2.8 $\times$ 10 ⁵ pp mL ⁻¹	Ogonowski et al. (2016)
	PE fragments 2.6 $\pm$ 1.8	100–2.25 $\times$ 10 ⁵ pp mL ⁻¹	Decreased feeding rate, and growth, increased mortality. 21-day EC50 reproduction = 8.6 $\times$ 10 ⁴ pp mL ⁻¹	Rehse et al. (2016)
	PE spheres 1–4	12.5–400 mg L ⁻¹	Ingestion and egestion noted, caused immobilization 96-h EC50 = 57.43 mg L ⁻¹	
	PE spheres 90–106	12.5–400 mg L ⁻¹	MP accumulated on water surface, not ingested, NEF	

<i>Daphnia pulex</i>	PS beads 2	$0.1\text{--}1 \text{ mg L}^{-1} \approx 1.4 \times 10^6\text{--}1.4 \times 10^7 \text{ pp mL}^{-1}$	Ingested up to $1.24 \times 10^6 \text{ pp ind}^{-1}$ or $0.89 \mu\text{g ind}^{-1}$ in 24 h. In 21 days, body burden up to $3.0 \times 10^5 \text{ pp ind}^{-1}$ or $2.43 \mu\text{g ind}^{-1}$ NEF survival or reproduction	Rist et al. (2017)
	PE beads 10–106 and PE fragments 10–75	$0.0001\text{--}10 \text{ g L}^{-1}$	24 h ingestion related to dose $33\text{--}50 \text{ pp ind}^{-1}$ in 24 h, Beads egested at higher rate than fibers 48-h EC50 mobility = 0.065 g L^{-1} for fragments	Frydkjær et al. (2017)
	PE beads 63–75	$25\text{--}100 \text{ mg L}^{-1} \approx 1.9 \times 10^6\text{--}7.6 \times 10^6 \text{ pp L}^{-1}$	Ingested $3.81\text{--}15.06 \text{ pp ind}^{-1}$ NEF survival or reproduction	Canniff and Hoang (2018)
	PE spheres 1–5	$1 \times 10^3\text{--}1 \times 10^7 \text{ pp mL}^{-1}$	18 °C 96-h NEC = $1 \times 10^5 \text{ pp mL}^{-1}$ More toxic at higher temperatures	Jaikumar et al. (2018)
	PE fragments 1–10	$1 \times 10^3\text{--}1 \times 10^7 \text{ pp mL}^{-1}$	18 °C 96-h NEC = $5.01 \times 10^4 \text{ pp mL}^{-1}$ More toxic at higher temperatures	Eltemsah and Bøhn (2019)
	PS beads 6	$5\text{--}300 \text{ mg L}^{-1}$	MP ingested and adhered to body surfaces and appendages. Decreased growth. 120-h EC50 immobilization = $35\text{--}52 \text{ mg L}^{-1}$	Jaikumar et al. (2019)
	PE spheres 1–5	$100\text{--}1 \times 10^5 \text{ pp mL}^{-1}$	21-day LOEC reproduction = 100 pp mL^{-1}	Schür et al. (2019)
	PE fragments 1–10	$100\text{--}1 \times 10^5 \text{ pp mL}^{-1}$	21-day LOEC reproduction = 100 pp mL^{-1}	
	PS beads 0.02 and 1.0	$2 \mu\text{g L}^{-1}$	Did not detect smaller fluorescent particles in Daphnia. Larger particles clearly visible in digestive tract. No fluorescence outside of gut.	
		2 mg L^{-1}	Fluorescence observed in lipid droplets and gut of Daphnia for both sizes of MP. Larger beads observed in gut. Fluorescence of lipids due to movement of dye, not pp.	
<i>Daphnia pulex</i>	PS 1	$0.1\text{--}600 \text{ mg L}^{-1}$	48-h EC50 immobilization = 66.97 mg L^{-1} 48-h LC50 = 87.83 mg L^{-1}	Zhang et al. (2019a)
	PS 10	$0.005\text{--}40 \text{ mg L}^{-1}$	48-h EC50 immobilization = $19\text{--}9.94 \text{ mg L}^{-1}$ 48-h LC50 = 291.69 mg L^{-1}	
	PET/PA fibers 10×2	10 pp mL^{-1}	31.7% mortality in 168 h Aggregates of MP and algae noted on antennae and carapace	Zocchi and Sommaruga (2019)
	PE beads 1–10	$0.01 \text{ mg mL}^{-1} \approx 2.2 \times 10^6 \text{ pp mL}^{-1}$	38% mortality in 168 h Aggregates of MP and algae noted on antennae and carapace	Jaikumar et al. (2018)
	PE spheres 1–5	$1 \times 10^3\text{--}1 \times 10^7 \text{ pp mL}^{-1}$	18 °C 96-h NOEC = $1 \times 10^5 \text{ pp mL}^{-1}$ More toxic at higher temperatures	Jaikumar et al. (2019)
	PE fragments 1–10	$1 \times 10^3\text{--}1 \times 10^7 \text{ pp mL}^{-1}$	18 °C 96-h NOEC = $1 \times 10^5 \text{ pp mL}^{-1}$ More toxic at higher temperatures	
	PE spheres 1–5	$100\text{--}1 \times 10^5 \text{ pp mL}^{-1}$	21-day LOEC reproduction = 100 pp mL^{-1}	
	PE Fragments 1–10	$100\text{--}1 \times 10^5 \text{ pp mL}^{-1}$	21-day LOEC reproduction = 100 pp mL^{-1}	
<i>Insects</i>				
Mosquito	PS beads 2 and 15	$50\text{--}200 \text{ pp L}^{-1}$	Larvae ingested MP—up to $256 \text{ pp larva}^{-1}$. MP transferred to pupal and adult stages. NEF survival or growth	Al-Jaibachi et al. (2019)
<i>Culex pipiens</i>	PS 2	100 pp mL^{-1}	MP ingested, average 5.8 pp ind^{-1}	Cuthbert et al. (2019)
Mosquito	PS 2	Fed <i>C. pipiens</i> that had been exposed to MP	MP found in predators, amount related to consumption rate	
<i>Culex pipiens</i>				
Phantom midge				
<i>Chaoborus flavicans</i>				
Midge	PE spheres 1–4, 10–27, 43–54, 100–126	500 pp kg^{-1} sediment ww	NEF on survival or growth with $100\text{--}126 \mu\text{m}$ MP. Decreased survival and growth in three smaller size classes, effects greatest for $10\text{--}27 \mu\text{m}$ MP. Emergence of adults decreased for all MP sizes	Ziajahromi et al. (2018)
<i>Chironomus tepperi</i>				
<i>Fish</i>				
African catfish	LDPE fragments < 60	$50 \text{ and } 500 \mu\text{g L}^{-1} \approx 1.4 \times 10^3 \text{ and } 1.4 \times 10^4$	MP not found in gill or liver tissues but gill and liver tissues were damaged. Altered levels of lipids and proteins in blood plasma	Karami et al. (2016)
<i>Clarias gariepinus</i>			Decreased gene transcription in brain tissue	
Common carp	PE	$1\text{--}2 \text{ mg L}^{-1}$	Changes in blood biochemistry indicating physiological stress and organ damage	Haghi and Banaee (2017)
<i>Cyprinus carpio</i>

Summary

The increased use of plastic materials by humans has led to the contamination of freshwater biomes with MP debris. MP particles are now found in the water column and sediments of lakes and rivers worldwide. While concentrations of MPs are generally fairly low <1 pp L⁻¹ in surface waters and <10 pp g⁻¹ sediment, higher concentrations are observed near urban areas, sewage plants and retention ponds where materials can settle. With the use of finer nets and sieves for sample collection, researchers are finding that fibers are more widespread and numerous than fragments or microbeads and pellets.

Although freshwater organisms do ingest MPs, the density of plastic in individual organisms in nature is generally quite low due to the ability of the organisms to depurate the plastic materials. Laboratory studies have found that MPs can adversely affect the metabolism, growth, reproduction, and survival of aquatic organisms, but generally at concentrations much higher than those found in nature.

Few studies have been done on the ability of MPs to accumulate toxic chemicals from freshwater environments and the kinetics of the release of these compounds to organisms upon ingestion is generally unknown under environmental conditions. Koelmans et al. (2016) found that MPs adsorb POPs in lower concentrations than natural media in the oceans. However, it should be noted that MPs are not biodegradable in a reasonable human time scale, and will be continuously concentrating toxic compounds from the aquatic environment.

Because MP pollution is an anthropogenic issue, we need to develop a way to decrease this environmental problem by enacting one of the UN's sustainable development goals "responsible consumption and production" (United Nations, 2015). By promoting education to raise the awareness of the general public to the negative effects of the indiscriminate use of everyday plastic items, we can produce a change in behavior regarding the consumption and uses of plastics.

Abstract

Springs ecosystems occur where groundwater reaches the Earth's surface, and are physically and biologically significant, complex, and highly socio-ecologically interactive ecosystems, particularly in arid regions. However, springs are threatened by intensifying human appropriation, contamination of groundwater, and surface habitat destruction. I review the literature and conceptual underpinnings of ecosystem ecology, springs distribution, typology, eco-evolutionary, and socio-cultural characteristics and processes in arid versus mesic/humid landscapes, and identify conceptual and data gaps. I estimate that the world's at least 2.3 million terrestrial springs produce at least 10.7 km³ of water/year. Most ecohydrogeological characteristics and processes discussed apply to all terrestrial springs across latitude and elevation; however, aridland springs differentially or more often have: (1) steeper environmental moisture and nutrient gradients between adjacent uplands, (2) distinctively different biotic assemblages; (3) higher occurrence of endemism and rare species in evolutionarily significant paleorefugia; (4) interrupted, losing-stream springbrooks, disconnectivity that retards non-native species colonization; (5) lower levels of flow and increased ephemeral flow; (6) reduced resiliency and more dynamism in vegetation development following disturbance; (7) greater susceptibility to anthropogenic impacts that leads to (8) loss of springs habitat and increased probability and incidence of extinction of springs-dependent species. These differences and greater conservation urgency elevate the need for improved stewardship of aridland springs. The study of aridland springs reveals much about the ecohydrology, distribution, ecological development and function, biogeography, ecological roles, and importance to humanity of springs everywhere, and the need and opportunities for enhanced stewardship of this highly endangered biome.

Introduction

Springs ecosystems are places influenced by the exposure and often the flow of groundwater onto the Earth's surface. Springs are widely recognized as being biologically productive, diverse, and socio-ecologically highly interactive ecosystems that supply high-quality water with spiritual and therapeutic qualities (Stevens and Meretsky, 2008; Cantonati et al., 2012; Glazier, 2014; Kreamer et al., 2015; Cantonati et al., 2020). Arid conditions prevail across about 29% of the Earth's surface, with deserts occurring in characteristic peri-equatorial as well as high latitude and high elevation settings (Kottek et al., 2006). While the values and significance of springs are widely recognized in arid regions, many of those same properties, processes, and values occur in springs everywhere on Earth, from profundal seafloor vents to tropical and high elevation environments. In part, the widely recognized

uniqueness and values of springs ecosystems is related to their internal constancy: individual springs often have remarkably constant or consistent flow, geochemistry, and temperature. However, springs across the Earth vary enormously in those characteristics, as well as in type, size, isolation, density within landscapes, biota, ecological processes, and human uses and values. Integration of these many physical, biological, ecological, and socio-cultural attributes and processes within and among springs makes their study a compelling and highly interdisciplinary field of ecohydrological study, one on which the pace of research is accelerating (Cantonati et al., 2020). Unfortunately, for all of their recognized value, springs are among the most threatened ecosystems, particularly in arid regions, with estimates of ecological impairment and loss commonly exceeding 70% in many landscapes (Stevens and Meretsky, 2008).

Below, I briefly review the growing literature on springs ecology and contribute data, illustrations, and examples to describe the conceptual underpinnings, distribution, typology, physical, biotic, eco-evolutionary, and socio-cultural characteristics and processes of springs, emphasizing those in arid regions. I use a “bottom-up” ecosystem approach to describe the physical and biological characteristics and processes, and anthropogenic uses of springs as ecosystems. I distinguish between those traits and processes in arid- and semi-arid regions as compared to those in more mesic humidity provinces. I primarily use examples from the arid American Southwest, but reference relevant studies from around the world. Aridland springs provide textbook cases of springs distribution, ecological development and function, biogeography, ecological roles, importance to humanity, and how stewardship can be improved. However, most of those ecohydrogeological underpinnings apply to all springs, both terrestrial and subaqueous (e.g., marine seafloor vent), and ranging from superarid (e.g., the Atacama Desert of northern Chile) to superhumid tropical rainforest regions. Thus, while the focus of this paper is on springs in arid regions, the processes, characteristics, and lessons to be learned apply to springs everywhere on Earth. Springs ecosystems have not previously been clearly recognized as an Earth biome; however, their globally distinctive characteristics across water quality and lentic vs. lotic gradients merit consideration of that designation.

Background Literature

Ecohydrogeological consideration of springs has a history rivaling that of humanity itself. Among the early recorded observations on springs, Aristotle (ca. 330 BCE) hypothesized on the source(s) of groundwater in Greece. Pliny the Elder (77 AD) related springs flow and geochemistry to vegetation production and structure throughout the Mediterranean region. Agricola and Perrault established the basic premises and laid the historical foundation for the science of hydrology (Perrault, 1674; Harter, 2003). Intensive research during the 20th Century was conducted on springs hydrogeology by Fuller (1904, 1910), Keilhack (1912), Steinmann (1915), Bryan (1919), Meinzer and Hare (1915), Meinzer (1923, 1927), Clarke (1924), Thienemann (1922), and Stiny (1933). On a parallel track in the 19th and 20th Centuries, the science of community ecology arose from the writing of Forbes (1887), Cowles (1911), Gleason (1926), Tansley (1935), and Lindeman (1942), with work on aridland hanging garden springs ecology by Woodbury (1939) and the codification of ecosystem ecology at Silver Springs Florida by Odum (1957). Reviews of springs ecohydrology have been presented by Alfaro and Wallace (1994), Williams and Danks (1991), and Botosaneanu (1998). In the present century, much additional review and new research on springs ecosystems has been conducted (e.g., Cantonati et al., 2007; Springer et al., 2008; Stevens and Meretsky, 2008; Springer and Stevens, 2009; Kresic and Stevanovic, 2010; Glazier, 2014; Kreamer et al., 2015; Stevens et al., in press). Among those studies, Glazier (2014) provided a detailed synopsis of available literature, information, and insights on the lexicon and approaches to classification of springs. Considerable recent focus also has been placed on springs ecosystem inventory, assessment, and management (e.g., Patterson and Cooper, 2007; Abele, 2011; US Forest Service, 2012; Knight, 2015; Stevens et al., 2016a,b). This research and new, innovative ecological tools, such as the use of eDNA to study springs biodiversity (e.g., Emerson et al., 2015) are expanding insight into springs ecosystem distribution and ecology, and stewardship needs, challenges, and solutions.

A Conceptual Ecosystem Model

Based on the above literature, springs are becoming increasingly recognized as important, physically-based, groundwater-dependent ecosystems (GDEs), occurring because of the exposure or emergence of groundwater (Eamus and Freund, 2006). Consequently, springs are regarded as “bottom-up” ecosystems, deriving their existence and structure from physical processes. Robust, “top-down” trophic cascades can develop at some springs (e.g., the highly endemized predatory invertebrate food chain at warm, stenothermic, mineralized and fishless Montezuma Well in Arizona; Blinn, 2008); nonetheless, physical interactions govern nearly all ecosystem dynamics in and around most springs.

Understanding the role of physical interactions affecting biological and anthropogenic interactions at springs is most easily envisioned through a springs conceptual ecosystem model (Stevens et al., in press; Fig. 1). In this model, bedrock and geologic structure, regional and long-term climate, and aquifer characteristics and processes set the stage for groundwater emergence. Springs sources emerge in a particular geomorphic setting (Meinzer, 1923; Alfaro and Wallace, 1994; Springer and Stevens, 2009), subject to a site-specific microclimate, and influenced by interactions between disturbance and productivity (e.g., Connell, 1978; Huston, 1994). These processes cumulatively create a landscape template, including soils and microhabitats, and generate “site hospitality” (sensu Stevens et al., in press) to potential colonizing populations. That habitat template is colonized through passive and active

Fig. 1 General conceptual model of springs ecosystems (simplified and redrawn from Stevens et al., in press). Black lines indicate natural interactions, while red lines indicate anthropogenic influences.

biogeographic processes and develops and changes over time, supporting species that interact to varying extent through competitive and feeding relationships, and generating up-trophic matter and energy transfers. Based on hydrogeologically-mediated geographic isolation and the intraecosystem intensity of biotic interactions, springs trophic structure in both arid and mesic regions can vary from simple systems that support a few widespread species to remarkably complex productive and dynamic systems (Odum, 1957; Blinn, 2008). Springs provide essential ecosystem goods and services, particularly fresh water in arid regions, and have exerted powerful influences on human evolution, and cultural and socio-economic well-being through time (e.g., Broad, 2006; Haynes, 2008; Gleick, 2010; Cuthbert and Ashley, 2014). However, all characteristics and processes of springs ecosystems can be appropriated, altered, eliminated, or created by indirect and direct anthropogenic activities. I use this conceptual model to organize the following sections in relation to the physical, biological, ecosystem process, human impacts, and stewardship of springs.

Hydrogeology and Geography

Source Waters

Groundwater expressed at springs sources is almost entirely derived from exogenic meteoric (atmospheric) precipitation (Figs. 1 and 2). Groundwater catchment basins develop in the context of regional and continental tectonics, which affect geologic structure and directs groundwater residence and flowpaths, and commonly range in area from < 1 to hundreds or thousands of km². Although generally mirroring surface catchment basins (Springer et al., 2017), notable exceptions exist in the Australian Great Artesian Basin (e.g., Ponder, 1986) and the North American Great Basin Desert. In the latter region, groundwater in the White River drainage in eastern Nevada, United States flows beneath at least three surface catchment basins before emerging in the Moapa River in the lower reach of this drainage system and then into the Virgin and Colorado River drainages (Thomas et al., 1996).

In temperate and high-elevation landscapes, snowmelt often is a primary source of groundwater, infiltrating and recharging local and regional aquifers (Fig. 2). In arid, lower latitude, and/or low-headwater settings, such as parts of North Africa, Australia, the North American Southwest, the Atacama Desert in central western South America, and elsewhere, groundwater is sourced from rainfall, with much recharge taking place in geologically structurally controlled stream channels, or exists in relictual paleo-groundwater aquifers that developed during Pleistocene or prior wet climate regimes. Depending on the region and setting, synoptic geology and structure, regional climate, and surface ecosystem characteristics, surface waters infiltrate into soils and subsurface strata. In arid and superarid environments, most precipitation is lost to evapotranspiration and only a small percent is available for groundwater recharge: Iorns et al. (1965) estimated that < 3% of precipitation was captured in aquifers in the arid Upper Colorado River basin in southwestern United States. Also contributing to groundwater supplies, a miniscule but geochemically informative quantity of connate (endogenic) water containing helium, carbon dioxide, and other compounds is derived from crustal degassing, and emerges from deep-aquifer springs (e.g., Crossey et al., 2009).

Limestone-dominated landscapes are renowned as settings in which groundwater moves through complicated pathways in the faults and fractures of karstic terrains, often with variable but short-duration residence times. Karstic terrain covers 12% of the Earth's surface, with many examples of highly productive aridlands karst springs (e.g., Huntton, 2000; Tobin et al., 2017;

Fig. 2 A general illustration of groundwater infiltration and flowpaths. Springs (filled circles) can emerge wherever gravity and stratigraphic tilt causes groundwater to reach the surface.

Chen et al., 2017). Worthington (2007) opined that karstic aquifers were characterized by “triple porosity”, with contrasting flow and storage properties in the matrix, structural fractures, and channels. His triple porosity karst aquifer model differs from other models that emphasize a range of flow from conduit to diffuse storage. Additional modeling complexity arises in karstic terrains with stacked aquifers and varying porosity and infiltration in relation to geologic structure. In such settings, normal concentration-overburden-precipitation groundwater modeling is improved by incorporating geographic information on non-randomly distributed, point-sources of infiltration, such as sinkholes and estavelles (Jones et al., 2019).

Ecosystem Structure and Classification

Springs emerge in a diverse array of forms and settings, a complexity that despite much excellent research on springs hydrogeology has long-eluded comprehensive classification (Stevens et al., in press). Steinmann (1915) and Thienemann (1922) recognized three types of springs by the velocity of water emerging from the source: lentic pool-forming limnocrenes, lotic flowing rheocrenes, and wet meadow or marshy helocrenes. These three “spheres of discharge” (sensu Meinzer, 1923) describe how springs flow emerges (the realm of interest of most hydrologists), but do not incorporate the surface linkage and related landforms and habitats that constitute the full subsurface-surface linked springs ecosystem (the realm of interest of ecologists; Cantonati et al., 2020). As a consequence, the lexicon used to describe springs has been largely based on physical hydrogeological properties or societal uses, rather than on the principles of ecosystem ecology, and have failed to provide unambiguous classification of the great array of springs ecosystem types that exist on Earth.

Springer and Stevens (2009) and Stevens et al. (in press) used source and outflow geomorphology and ecosystem ecology to propose 13 major types of terrestrial springs. Their classification, illustration, and dichotomous key distinguishes among these springs ecosystems, including: simple exposure of the groundwater table; cave springs; geysers; gushets (madicolous flow cascading down cliff faces); fluvial, upland, and blister wetland wet meadow helocrenes; ice hill (i.e., pingos), organic, and carbonate mound forms; floodplain and upland hillslope springs; artesian fountains; hanging gardens (Welsh, 1989); hypocrenic expressions of groundwater through wetland vegetation; pool-forming springs (limnocrenes); springs emerging in stream channels (rheocrenes); as well as no-longer-flowing paleocrenes. Those authors note that many springs have dominant and also subdominant typology (e.g., a gushet emerging in a hanging garden), and that English adjectival attribution of secondary and sometimes tertiary types was appropriate (e.g., a natural pond in a wet meadow spring is a limnocrenic helocene), but they recognize that such linguistic subtleties may be more awkward in other languages.

Nearly all of the springs types mentioned above exist in aridland and mesic environments, perhaps excepting natural geysers, nearly all of which occur in mesic environments, such as Yellowstone National Park in Wyoming and New Zealand (e.g., the Rotorua geothermal field). Another exception, hanging gardens are perhaps best represented in arid, largely geologically undeformed sandstone-dominated landscapes, such as those in southern Utah and northern Arizona. Biotic analyses among springs types reveal characteristic patterns of vegetation habitat structure and composition, as well as human uses (e.g., Sinclair, 2018). The geomorphic configuration of springs ecosystems at and downstream from the point of emergence results in ecological

differentiation of their biotic assemblages and their human uses and impacts, and much research is needed to more clearly distinguish these characteristics and processes to improve springs stewardship in both arid and mesic environments.

The above authors also note that any springs type can be created or altered through anthropogenic manipulation of flow or of site geomorphology. Abandoned artesian well bores can produce fountains or even geysers (e.g., the Tecopa Bore in California, [Wamalwa et al., 2011](#); Crystal Geyser in central Utah, [Han et al., 2013](#)). Another common anthropogenic springs manipulation throughout the world involves excavation of ponds for livestock watering in wet meadows, creating anthropogenic limnocrenic helocrenes. Sewage effluent-fed streams have become common urban features (e.g., Las Vegas Wash in southern Nevada), often functioning as hillslope or rheocrene springs. Also, the release of water from a dammed stream or river can be regarded as an anthropogenic rheocrene, ecological alterations that exert potentially large impacts on downstream ecosystem ecology (e.g., [Ward and Stanford, 1983](#)). A cave-like excavation into a cliff-emerging springs source to focus flow is called a “qanat”, a common feature throughout the world. In relation to springs classification, [Stevens et al. \(in press\)](#) recommended that human-created springs be classified based on their ecological function, with the modifying term “anthropogenic” applied as a secondary or tertiary adjective.

Geomorphic Microhabitats

Adding to their geomorphic and biological diversity, springs ecosystems often are composed of complex mosaics of microhabitats. Springs ecosystems, such as large hanging gardens or gushets may support a dozen microhabitats, each of which support discrete, sometimes interacting assemblages of flora and fauna ([Stevens et al., in press](#)). Common microhabitat types encountered include channels and terraces, pools, wet walls, and source caves. While different suites of these geomorphic microhabitat landforms are characteristic of specific springs types, each microhabitat has properties that influence its biological colonization and development, and each can undergo microhabitat-specific changes over time, such as the development of travertine dams. The colonization history and variation in the microhabitat array contribute to the high levels of individuality recognized for these generally small, but often complex ecosystems. However, insufficient within-springs inventory data exist at present to determine differences between microhabitat arrays in arid versus mesic landscapes.

[Stevens et al. \(2016b\)](#) proposed calculating springs geomorphic complexity using the Shannon-Weiner diversity metric ([Shannon, 1948](#)) based on the number and relative area of springs-associated microhabitats, and [Springer et al. \(2015\)](#) and [Sinclair \(2018\)](#) demonstrated positive correlations between geomorphic diversity and plant species richness at springs in both arid and semi-arid landscapes in mesic and arid portions of western North America, respectively. Additional analyses are needed to clarify the relationships between geomorphic and biological diversity within and among springs types.

Springbrooks (springs runout channels) are among the most prominent springs microhabitats. Usually driven by gravity, groundwater is exposed at the Earth’s surface at springs, often flowing across the land and merging with other aquatic ecosystems. Springbrooks and their associated riparian and peripheral environments are defined as springfed stream channels that are more strongly influenced by springs flow than by surface flow. The length of the springbrook can be defined as the point at which surface processes begin to dominate over the springs influences on the channel geomorphology and habitat, and as the point at which a “zero order” springs channel becomes a first order stream (sensu [Strahler, 1957](#)). Springbrooks typically are linear-erratic, slightly incised channels ([Griffiths et al., 2008](#)), extending downstream to where surface flow-influenced channel meandering, terrace formation, and other characteristic stream geomorphic landforms become apparent, along with changes in biodiversity ([Stevens et al., 2005](#); [Dumnicka et al., 2013](#); [Morrison et al., 2013](#)).

Geography: Abundance and Density

Springs are abundant on Earth, occurring both on land and in submarine settings, but the absolute number and density of springs varies enormously among countries and continents ([Fig. 3](#)). Close examination of distribution maps indicates that springs emerge in greater density in topographically complex landscapes. In the case of the United States, springs density is high in the major mountain ranges (Appalachian, Ozark, Sierra Nevada, and Rocky Mountain Ranges), but relatively low in flatlands, such as the southern Great Plains. This is intuitive, because springs are more likely to emerge where strata are tiled and aquifer edges are exposed in escarpments and mountain ranges ([Stevens and Meretsky, 2008](#)).

Estimates of springs abundance on Earth have ranged up to 50 million, but systematic mapping data are not available for most regions and continents (e.g., particularly Asia, Africa, and South America). [Glazier \(2014\)](#) presented data on terrestrial springs density from around the world that can be used to crudely estimate overall density and test whether springs density/km² varies between arid and semi-arid, versus mesic and humid landscapes. His data indicate that springs density is generally low but is spatially highly variable (median = 0.01 springs/km², $N = 42$ landscapes, 1 sd = 0.79 springs/km²). Due to the high variance among landscapes and the 30-fold difference between median and average density (0.30/km²), global springs density values, tripling the estimated grand median value to 0.03 springs/km² produces a conservative prediction of 2.5 million terrestrial springs on Earth (planview land area = 1.48×10^8 km²). Although a large number, it is more than an order of magnitude lower than some previous estimates of springs abundance on Earth.

Much of the reason for the large uncertainty in springs density involves variation in the accuracy of mapping data, which often are incomplete and inaccurate, even in developed nations such as the United States, and which is abundantly apparent between regions and nations ([Fig. 3](#)). For example, previously published data on the abundance of springs in Nevada, the US’s driest state,

Fig. 3 A preliminary map of global springs distribution. Differences among countries are largely due to the quality and availability of mapping data.

indicated that 4179 springs existed there (Glazier, 2014). Over the past decade, the Museum of Northern Arizona's Springs Stewardship Institute (SSI 2019) mapped and inventoried many Nevada springs, and now reports an estimated 27,000 Nevada springs, a density of 0.095 springs/km² and 6.5-fold more than previously reported (Fig. 4). Nevada presently has the highest density of springs in the United States (SSI 2019), a result of the many hundreds of Basin and Range Geologic Province mountain ranges with likely thousands of small aquifers that characterize the state. Intensive springs inventory programs elsewhere in the Great Basin similarly have greatly increased the number and density of springs in large landscapes (e.g., Junghans et al., 2016). Profundal seafloor springs are primarily distributed along tectonic spreading ridges, although coldwater submarine seeps also have been

Fig. 4 Springs of the Great Basin, United States, including those known to support tiny but often highly locally endemized springsnail species, such as *Pyrgulopsis* (inset), more than 120 species of which exist, primarily in one or only a few North American springs (Hershler and Liu, 2017).

identified (Joseph, 2017). In contrast, springs density estimates decrease by an order of magnitude or more in tectonically quiescent regions, such as the American Great Plains (Stevens and Meretsky, 2008), although prairie pothole exposure springs are abundant in the central and northern Great Plains (Van der Valk, 1989).

Springs density can be expected to be greater in more humid regions. Glazier's (2014) data indicate a trend supporting this premise: springs density in mesic regions (median = $0.019/\text{km}^2$, $N = 24$, 1 sd = 1.007) was 2.5-fold greater than that in arid and semi-arid regions (median = $0.007/\text{km}^2$, $N = 18$, 1 sd = 0.042). However and again, high levels of spatial variability and inconsistent mapping data obscure the significance of this pattern, and more accurate regional and national springs inventories are needed for a more complete test of this basic assumption.

Discharge

Springs and seeps are abundant in many landscapes and contribute substantially to local and national water budgets throughout the world (Glazier, 2014). Some of the Earth's largest terrestrial springs include: mesic New Zealand's South Island Te Waikoropupū Spring (average discharge = 1.4×10^4 L/s); and large aridland Northern Hemisphere springs, such as Syria's Ra-El-Ain Spring (average discharge, $Q = 3.63 \times 10^4$ L/s) and Turkey's Dumanli Spring (average $Q = 5.03 \times 10^4$ L/s; Karanjac and Günay, 1980; Alfaro and Wallace, 1994). At least five large European and African cities rely virtually exclusively on large springs for urban water supplies (Stevanovic, 2010; Glazier, 2014; Stevens et al., in press); and other large springs are described in Meinzer (1927) and Stevanovic (2010). However, most springs produce little flow, generally between 0.1 and 1.0 L/s, and many desert springs are ephemeral, flowing only seasonally or only after wet periods. The following examples illustrate these patterns. (1) A recent inventory of 97 springs in Nevada reported that the mean Q was 0.2 L/s, with a maximum Q of 186 L/s at one site (SSI 2019). (2) In one of the few comprehensive national analyses, Pérez (1996) summarized the flow of springs in Spain, reporting a grand median Q from more than 25,000 springs of 0.7 L/s and a grand mean $Q = 12$ L/s. Those data indicated that 24,500 (98%) of the springs had flows < 35 L/s but those springs produced only 45% of the cumulative discharge, while the remaining 2% of springs contributed more than half of that nation's springs flow. (3) Stevens et al. (2016a) examined springs discharge in Arizona, reporting a grand median Q of 0.14 L/s and a grand mean of 19.8 L/s among 1342 springs. Extrapolating from those flow data to the state's estimated 10,300 reported springs suggested that springs produce 17,176 L/s ($542 \text{ km}^3/\text{year}$) of discharge, roughly 6% of the 2012 state water budget. Arizona springs are used to support wildlife, livestock production and other agricultural activities, as well as providing domestic and some urban water supplies. (4) The single, small Wittmer Spring on the arid Galápagos Island of Floreana (ca. 0.5 L/s) has been the primary source of freshwater and social intrigue since its discovery in the late 18th Century (e.g., Treherne, 2002). (5) Many springs, large and small, are ephemeral, a flow pattern recognized by Glazier (2014) as "sipeocrenic". For example, La Fontaine Spring flows seasonally and erratically, providing baseflow for the La Morgue River in France (Stevens et al., in press). Thus, large springs (median $Q > 500$ L/s) make up far fewer than 1% of the total global population of springs, but those springs are unquestionably important water sources. However, the vast number of much smaller springs provide critically important local sources of water for biodiversity and for many human populations, particularly in arid regions.

At present global terrestrial springs discharge estimates are extremely crude. However, if 98% of the Earth's estimated 2.3 million terrestrial springs have a median discharge of 0.1 L/s, they would produce approximately 7.1 km^3 of water/year. If that is half of the Earth's total terrestrial springflow, and 2% of the springs are large and contribute half again as much flow, I very conservatively estimate that terrestrial springs produce at least $10.7 \text{ km}^3/\text{year}$ of freshwater discharge; however, I recognize that the total global discharge could easily be twice that estimate. Clearly, many more data are needed to provide a more accurate estimate.

Water Quality

Water quality (temperature and geochemistry) changes as water infiltrates through the soil and passes into the subsurface environment, where it is affected by latitude, elevation, bedrock geology, infiltration pathways, aquifer geology, emergence forcing mechanisms, and flowpath duration. Variation in the quality of groundwater emerging from springs is generally low, while variation among springs is enormous, and much variation in water quality can exist within individual aquifers, such as the large Coconino aquifer in northern Arizona (Bills and Flynn, 2003). Springs water quality can affect the source geomorphology (e.g., at mineral-depositing springs, or through channel formation), its biotic assemblage composition and diversity (e.g., Sinclair, 2018), as well as human uses and the impacts we exert upon them (Figs. 1 and 2).

Springs water temperature characteristics have been described and summarized primarily in relation to mean annual air temperature, ecology, or human sensation, and range from near freezing to hyper-thermal sea floor vent springs (e.g., Waring, 1965; Alfaro and Wallace, 1994; Springer et al., 2008; Glazier, 2014; Stevens et al., in press). Groundwater temperatures in non-thermal and warm springs generally reflect residence time and flowpath length (Fig. 2), and influence food chain length (Glazier, 2012). Shallow, high elevation aquifers in both arid and mesic landscapes generally express cool to cold, low ion content water temperatures, reflecting cooler ambient conditions and short flowpaths and residence times. Low elevation aridland springs generally express warmer, mineralized water temperatures due to ambient climate, often longer flowpaths, and protracted duration of flow travel times (e.g., Thomas et al., 1996; Johnson et al., 2012). However, karstic terrains across latitude and elevation often are characterized by rapid passage of infiltrating water and delivery of cooler waters to lower elevations, such as occurs in springs emerging from the Redwall Aquifer in northern Arizona (Tobin et al., 2017). In contrast, geothermal conditions reflect groundwater interaction with magmatism, and potentially rapid, pressurized movement of groundwater through aquifers. Many thousands of

geothermal springs have been developed globally for recreational and therapeutic uses, making it increasingly difficult to find undeveloped sites at which to study hot springs ecosystem ecology (but see Brock, 1978; Morrison et al., 2013).

Springs geochemistry studies have identified a wide array of important ion constituents and water quality variables that characterize springs water quality, including borate, calcium, carbonate, chloride, dissolved oxygen, magnesium, methane, potassium, rare earth elements, silica dioxide, sodium, stable isotopes, sulfate and sulfide, nutrients, and combinations thereof, as well as alkalinity, bacteriology, biological oxygen demand, nutrients, pH, turbidity, water color (Peale, 1886; Palmer, 1911; Clarke, 1924; Fitch, 1927; Meinzer, 1927; Futak and Langguth, 1996). Futak and Langguth (1996) classified Greek springs as: normal earth alkaline hydrogen-carbonatic; normal earth alkaline, hydrogen-carbonatic-sulfatic waters; and enriched alkali earth alkaline hydrogen-carbonatic waters. Geochemical analyses have been successfully used to describe aridland karstic springs (e.g., Shuster and White, 1971; Bonacci, 1993; Huntoon, 2000; Crossey et al., 2009; Hershey et al., 2010; Springer et al., 2017), but those studies do not illuminate differences among humidity provinces. The factors that affect springs water temperature (above) also generally affect geochemistry, so that lowland aridland springs are more likely to be mineralized than those at higher elevations (e.g., Ledbetter et al., 2016); however, global characterization of geochemical differences between arid and mesic regions remains outstanding due to complex interactions in relation to tectonism, geologic province, as well as latitude, landscape position, regional geology and climate, springs type, and a host of other locally important variables.

Although groundwater passage results in geochemical alteration of the water, the oxygen and hydrogen isotopes of the original surface precipitation are conserved, allowing groundwater age and residence time to be estimated. However, springs flow is typically comprised of both longer-distance, as well as locally-recharged groundwater, complicating the dating of the emerging water. Nonetheless, groundwater age analyses show that groundwater flowpath duration ranges from <0.01 to 10^6 year, with long flowpaths of paleowater noted in arid regions (e.g., Ponder, 1986 in the Great Artesian Basin of Australia; Thomas et al., 1996 in the North American Great Basin Desert).

Habitat and Area

Springs habitat area includes the area of open water, wetlands, and riparian lands directly influenced by springs. Open water pool, stream, and cascading habitats each can support discrete biotic assemblages, which also transition downstream to the point that surface flow begins to dominate stream processes (e.g., Morrison et al., 2013). Open water habitat often makes up only a small percentage of the overall landscape influenced by groundwater emergence in springs ecosystems, the exceptions being limnocrenes and some rheocrenes and mound springs. Most springs habitat area is dominated by saturated or moist soils, generating some to much wetland and riparian habitat. The percent of open water habitat is likely somewhat less at aridland springs due to higher productivity, vigorous emergent plant growth, and greater evapotranspiration rate; however, thorough analyses of such microhabitat relationships require far more data than currently are available. Nonetheless, springs-supported wetland and riparian habitats are of primary importance as habitat for both springs-dependent and upland species as sources of habitat and food, particularly in water-limited arid regions. Depending on springs type, riparian plant zonation (and likely that of other biota) occurs in a radiating pattern, changing outwards from the source from aquatic to wetland to peripheral riparian to upland species composition (likely tightly related to xylem water potential characteristics of the plant species present; Merigliano, 2005). Vegetation structure, and function also are strongly dependent on springs type (Sinclair, 2018). For example, (1) marshy helocrenes tend to be dominated by wetland graminoids, and riparian herbs and shrub species in both arid and mesic regions; (2) hanging gardens are occupied by a distinctive flora of tightly adapted and endemic species; and (3) arid regions support helocrenic palm oases, but not swamp forests.

Individual springs occupy a median area of approximately 0.05 ha in Nevada, cumulatively occupying up to a maximum of 0.004% of the land area of that state (SSI 2019), and likely no more than 0.005% of the entire coterminous US land surface area. Thus, despite their considerable influence on local ecology across the terrestrial world, the total habitat area of springs is extremely small. However, few data are available to determine whether springs area differs in mesic as compared to arid regions. Overall, springs make up only a tiny fraction of the planet's arid as well as mesic surface area, but as described below, they exert a disproportionately large influence on the world's bio-cultural ecology than would otherwise be predicted based on their generally small flow and habitat area.

Springs Biology

Biogeography

Springs function as insular patches of habitat, and therefore are natural laboratories in which to examine the role of passive and active biogeographic processes. Assemblage comparisons of passively dispersing biota at springs indicate that some taxa are prone to orderly biogeographic patterns of colonization, while others are not. For example, Kodric-Brown and Brown (1993) and Ríos-Arana et al. (2018) reported highly structured Australian fish and Chihuahua Mexico rotifer assemblages, respectively, with strong patterns of assemblage nestedness. Nielson et al. (2019) reported analogous patterns of nestedness in non-native weedy plant colonization of springs in Alberta, Canada. In contrast, Weissinger et al. (2012) reported only weak nestedness among macroinvertebrates in Utah sandstone springs. Thus, at least in some cases, interactions between isolation and patch size influence species richness and assemblage characteristics.

In contrast to passively-dispersing organisms, larger volant and non-volant invertebrates and vertebrates engage in non-random habitat selection of springs. This is readily apparent among predators ranging from aquatic beetles to large predators and humans using springs as ambush sites (e.g., Haynes, 2008). For example, I found 10 species of aquatic predaceous beetles in an extremely isolated, 1 m² *Canis latrans*-excavated exposure springs (a “coyote pozo”) at the head of the Gulf of California. Many aquatic predatory insects actively search for rare freshwater habitats in arid regions, arriving singly or in large flocks (e.g., Stevens et al., 2007). Additionally, migrating avifauna and other volant and non-volant terrestrial organisms in arid regions may preferentially use lacustrine, palustrine, stream, and springs habitats as stop-over or stepping stone habitats, and are at risk under a drying climate in landscapes such as the arid Great Basin in western North America (Haig et al., 2019). Also, the role of springs water quality in larval fish imprinting and spawning migration is recognized and exploited among salmonids (Ueda, 2011), and may be widespread among other freshwater and anadromous fish taxa. Understanding such processes may increase appreciation of the role of springs within watersheds.

Springs-Dependent Biodiversity

Springs are widely regarded as hotspots of biodiversity that support rare, endemic, and often critically endangered springs-dependent (crenobiontic) species (e.g., Williams and Danks, 1991; Botosaneanu, 1998; Ponder, 1986; Fensham and Fairfax, 2003; Unmack, 2001; Cantonati et al., 2007; Unmack and Minckley, 2008; Martens et al., 2010; Rossini et al., 2018; Stevens et al., in press). Endemism within aridland springs is particularly renowned, including that of diatoms, invertebrates (e.g., truncatelloidean springsnails; Hershler et al., 2014), and fish (e.g., Unmack, 2001; Minckley and Unmack, 2008; Rossini et al., 2018). For example, the Great Basin White/Moapa River drainage with its long, slow deep-aquifer springs sourcing, collectively supports at least 30 endemic and rare invertebrate and fish species (e.g., Hershler and Liu, 2017; Southern Nevada Water Authority, 2019).

Phylogenetic research has revealed the hydrobiid aquatic springsnail assemblage of Death Valley, California has arisen due to periodic post-Miocene habitat connectivity stemming from repeated endorheic lake expansion and contraction, coupled with erratic dispersal events (Hershler and Liu, 2008). Such studies demonstrate the extent of environmental change over geologic time that results in high levels of endemism in aridland springs.

While an exhaustive list of the world’s springs-dependent and endemic species remains outstanding, several regional studies indicate the existence of hundreds to thousands of springs-dependent taxa globally, with a disproportionately high percentage of those species found in aridland springs. Among existing literature, the following taxa and examples have been shown to be reliant on springs, particularly in arid regions:

- Plants
 - Diatoms (e.g., Lai et al., 2019)
 - Vascular plants (e.g., Texas Wild Rice (Poaceae: *Zizania texana*), endemic to the San Marco River); flowering shrub (*Flaveria mcdougallii* (Asteraceae), endemic to alkaline springs in central Grand Canyon, Arizona); Australian endemic springs plants and assemblages (Rossini et al., 2018; Australian Biological Resources Study, 2020)
- Platyhelminthes flatworms (Schockaert et al., 2008)
- Gastropoda (e.g., Hydrobiidae springsnails; Ponder, 1986; Hershler and Liu, 2017)
- Arthropoda
 - Crustaceans—subterranean freshwater Isopoda, surface-dwelling Anostraca, Amphipoda (e.g., *Hyaella* spp.), and microcrustaceans (e.g., Ríos-Arana et al., 2018)
 - Chelicerata—aquatic mites, spiders (e.g., Gerecke and Di Sabatino, 2007)
 - Insecta—Odonata (Stevens and Bailowitz, 2009), Ephemeroptera, Plecoptera, Hemiptera (e.g., Belostomatidae, Naucoridae, Nepidae; Stevens and Polhemus, 2008), Coleoptera (e.g., Dryopoidea; Shepard, 1993), Diptera, Trichoptera
- Fish—Goodeidae, Cyprinodontidae, and Cyprinidae in the United States (Minckley, 1973; Sigler and Sigler, 1986); Plotosidae, Gobiidae, Eleotridae, and Atherinidae in Australia (Unmack, 2001; Rossini et al., 2018)
- Amphibians—e.g., Barton Springs Salamander (*Eurycea sosorum*) in Texas, Relict Leopard Frog *Lithobates onca* in Nevada
- Reptiles—several southwestern US *Thamnophis* garter snakes (Brennan and Holycross, 2006)
- Mammals—Preble’s meadow jumping mouse (*Zapus hudsonius preblei*; Trainor et al., 2012), Amargosa vole (*Microtus californicus scirpensis*)
- Birds—American Dipper (*Cinclus mexicanus unicolor*), which commonly nests behind springfed waterfalls in the Southwest (Stevens et al., in press).

Springs Assemblages

Depending on springs type, location, landscape context, and adjacent biome interactions, springs biotic assemblages can be highly dynamic, or can be remarkably constant habitats, supporting closely adapted and highly endemized faunal assemblages. Nekola (1999) distinguished between weedy species-dominated neorefugia versus long-term stable paleorefugia, which exist for evolutionarily significant time periods and support relict assemblages. Paleorefugial springs include many stable, deep-aquifer springs in arid regions that support high concentrations of unique and rare species (e.g., Montezuma Well in Arizona, Blinn, 2008; Ash Meadows

in Nevada, [Patton et al., 2008](#); Cuatro Ciénegas in northern Mexico, [Unmack and Minckley, 2008](#); Dalhousie and other mound springs in Australia, [Ponder, 1986](#)).

Deep-aquifer/long flowpath paleoregional springs have sufficient stability over evolutionary time to allow the interaction and evolution of complex assemblages of highly endemized taxa. Montezuma Well in central Arizona is a 17 m-deep, 120 m-wide, highly mineralized, fishless, collapsed carbonate mound spring pool. It supports high algal primary productivity, and an endemic amphipod, *Hyalella montezuma* ([Blinn, 2008](#)). During the daylight hours the amphipod serves as prey for three taxa of predatory insects (including one endemic water scorpion), which occupy the vegetated margins of the pool. To avoid these visually-feeding insects the amphipod population moves out to the center of the pool during the day. At night, four species of leeches (including the endemic genus *Motobdella*) swim up from a zone of benthic floc to feed on amphipods they detect in the water column, chasing the amphipods back to safety of the margin vegetation. Thus, predation pressures cause the planktonic amphipods to undertake a remarkable daily migration. With at least six endemic species, Montezuma Well has the highest concentration of unique species in any single springs ecosystem in North America, to my knowledge. Naturally high concentrations of arsenic there may facilitate the evolution of endemism, a process that warrants further study ([Compton-O'Brien et al., 2002](#)). However, all of that ecosystem's endemic species are invertebrate animals, and except for a single diatom species, no endemic plant taxa exist there. The pattern of substantially greater levels of localized endemism among springs invertebrates than among vascular plants is apparent throughout North America, Europe, and Australia, and points to substantial differences in gene flow patterns and evolutionary processes between plants and animals.

Although the composition and structure of springs vegetation has been widely accepted as a monitoring metric, vegetation dynamics are largely a function of springs type ([Sinclair, 2018](#)). Slope angle, flow perenniality, and scour frequency all vary with springs type, limiting the utility of vegetation as a metric of ecological integrity in some hillslope and gusset springs, and most rheocrenes. For example, wetland vegetation cover at one gusset I studied in Grand Canyon varied from 20% to 90% over a three-year period due to rockfall and flood scour ([Grand Canyon Wildlands Council, 2004](#)). Such variation is perhaps more likely to exist in aridland springs, where storm intensity and frequency are highly variable. Therefore, while useful for less disturbed sites, springs vegetation cover may not be universally useful as a monitoring metric.

Non-native species are commonly encountered at springs and have been the subject of considerable concern in the conservation and restoration of springs and native endemic SDS. Intuitively, one would expect that springs habitats that are strongly dominated by native vegetation would be resilient to invasion by non-native plant species; however, the great dispersal capacity of many weed species means that even slight natural or anthropogenic disturbances at springs that expose moist soil provide habitat for non-native plant establishment. Thus, non-native plant species like several grasses (Poaceae), salt-cedar (*Tamarix* spp), Russian olive (*Elaeagnus angustifolia*), proliferate at springs, and non-native plant species richness often appears to be positively correlated with the richness of native species (e.g., [Stevens and Ayers, 2002](#)). Non-native fauna that may negatively affect native faunal SDS in the American Southwest include: *Potamopyrgus antipodarum* New Zealand Mudsnails, *Melanoides tuberculata* Red-rimmed Melania freshwater snails, cambarid crayfish (e.g., *Procambarus clarkii*), *Lithobates catesbeiana* American Bullfrogs, a large assemblage of non-native aquarium and game fish species ([Sada, 2008](#)), as well as managed and feral livestock. Oftentimes, environmentally eurytolerant non-native species are able to colonize habitat occupied by steno-adapted SDS, making the invaded springs habitat far more competitive for the native species. But in contrast, non-native species are not always necessarily detrimental to endemic SDS. For example, growing evidence indicates a positive relationship between native, highly endemized truncatelloidean springsnails and non-native watercress (*Nasturtium officinale*) throughout the United States.

Ecosystem Ecology

Ecological Roles of Springs

Springs play important ecological roles in many of the landscapes in which they exist, including providing critical flow, water quality and other habitat components, and ecosystem goods and services, all of which are of elevated importance in arid regions. Our studies indicate that every natural stream in non-ice-dominated landscapes on Earth, and particularly those in arid and low-headwater regions, is sourced by springs, helocrenes, or from lakes, many of which also are limnocrenic ([Junghans et al., 2016](#); [Miller et al., 2016](#)). [Gomi et al. \(2002\)](#) and [Stevens et al. \(in press\)](#) recognize that springs are fundamentally important in stream networks, with the latter authors recommending that springs be considered as “zero order” streams (sensu [Strahler, 1957](#)), playing an essential sourcing role in surface water ecology. However, aridland springbrooks often are losing systems, flowing for limited, potentially seasonally varying distances before sinking back into the ground. Disconnection from downstream waters can protect desert springs from invasion by non-native aquatic species, such as exotic crayfishes, amphibians, and released aquarium and game fishes. Thus, from a conservation standpoint, interrupted habitat connectivity may be a highly advantageous, natural characteristic of aridland springs.

Despite their generally small discharge, springs ecological function and habitats constitute an enormous but largely overlooked role in synoptic upland and stream ecology in both arid and mesic environments. Springs have been described as keystone ecosystems, small but highly ecologically interactive ecosystems, without which both internal (allochthonous) and synoptic upland (allochthonous) ecological activity and processes are reduced or lost ([Perla and Stevens, 2008](#)). Their study revealed high levels of inter-ecosystem interactivity around Seaman Spring in arid southern Utah. That ecologically attractive and interactive aridland habitat patch generated extensive autochthonous carbon while also providing habitat and food resources for upland biota. While

such measurements are rare, I predict that the keystone ecosystem function is a much more prominent characteristic of arid land springs than it is in regions with higher levels of humidity, where water is less of a limiting resource. Strong differences in the ecological roles of springs likely exist in arid versus mesic environments, and in the role of springs in relation to uplands across climate zones and under changing climates. Of particular interest, climate change adaptation requires recognition of the role of springs as potential refugia, and whether and how these ecosystems will respond to increasing environmental stress (Cartwright et al., 2020).

Trophic Complexity

Lindeman's (1942) concepts of ecosystem ecology were ground-truthed at Silver Springs in Florida (Odum, 1957), but springs ecosystem ecology has been tested at relatively few other sites, which typically are limnocrone, mound, or geothermal springs. If sunlight is not obstructed by cliff walls, overhanging rocks, or tree cover, the net annual primary productivity (NAPP) of the aquatic domain of a springs ecosystem can exceed $5 \text{ kg C/m}^2/\text{year}$, equal to or exceeding the gross annual primary productivity of adjacent wetlands (Odum, 1957; Blinn, 2008; Threvis et al., 2007). Terrestrial geothermal springs, and even chemautotroph-driven seafloor vent springs also show remarkably high levels of NAPP (e.g., Brock, 1978; Morrison et al., 2013; McNichol et al., 2018). In contrast, NAPP in arid lands is commonly 2–3 orders of magnitude lower, and in harsh, virtually rainless settings, such as the Chilean Atacama Desert, may be virtually zero. Thus, a key defining feature of aridland springs is the steepness of the moisture gradient from the springs into the adjacent uplands. A linear distance of less than a meter and an elevation rise of only a few centimeters above the water surface may be sufficient to transform: NAPP, soil temperature, quality, and nutrient availability; vegetation composition, zonation, structure, and function; faunal composition; and springs-upland eco-interactivity across the aquatic to xeric moisture gradient.

Although poorly studied, springs in humid regions are expected to demonstrate much shallower environmental gradient slopes, with only gradual upslope transitions in those variables, relatively low dissimilarity between springs riparian and upland vegetation characteristics, and lower faunistic differences and springs-uplands interactivity. Springs ecological interactivity overall, and whether the springs-to-uplands environmental gradient steepness is continuous or is subject to thresholds in arid versus humid landscapes remain important research topics, particularly in the face of changing climate.

Subsidy Exchange

Subsidy exchange in springs involves consideration of all matter and energy interactions and NAPP across space and time, of which the carbon budget can serve as a suitable surrogate (e.g., Foley et al., 1996; Figs. 1 and 5). With solar energy as the primary source of energy, terrestrial springs receive allochthonous organic carbon and nutrients through atmospheric, gravity and animal-transported (including invertebrate and vertebrate) sources from adjacent upslope, lateral, atmospheric, and upwelling groundwater sources. Springs internally produce aquatic and riparian autochthonous carbon, recycling it, and potentially exporting it laterally, downstream through the springbrook, vertically into the atmosphere, into adjacent riparian soils, and into the hyporheic zone, as

Fig. 5 A conceptual model of ecological subsidy exchange in aridland springs. (Upper graph) a low-elevation or south-facing upland hillslope springs ecosystem that is not shaded by cliffs or forest canopy. (Lower graph) a high elevation or north-facing upland hillslope springs ecosystem that is heavily shaded by forest canopy or by adjacent cliffs. Line widths indicate relative strength of effect, and diagonal lines represent lateral subsidy exchange, whereas vertical lines indicate atmospheric or hyporheic exchange.

well as a tiny fraction that may be returned into the aquifer. As mentioned above, the steepness of the moisture gradient in aridland springs distinguishes them from the gradient slopes in humid regions; however, aridland springs occur in a wide array of geologic, geomorphic, elevation, and climate settings, in open as well as heavily shaded environments. While upland allochthonous NAPP and C inputs may be relatively low in arid regions, unshaded aridland springs in unforested, open settings with unobstructed direct solar radiation have increased autochthonous NAPP and nutrient spiraling, extending downstream through the springbrook (Fig. 5A). However, desert springbrooks often are truncated as losing streams, with decreasing aquatic NAPP and trophic exchange over distance, and also often with carbonate-cemented channel floors that limit hyporheic interactivity (Fig. 5, upper graph).

In considerable contrast, sunlight-limited, shaded, north-facing, forested springs at higher elevations have reduced growing season length and consequently relative autochthonous carbon exchange and NAPP may be greatly reduced. In such springs, nutrient spiraling and productivity of the springbrook may remain equal or increase over distance downstream, and hyporheic zones may often remain interactive due to the general absence of channel floor cementation (Fig. 5, lower graph). Aquatic macro-invertebrate and wetland plant species richness, springs-upland wildlife interactivity, and endemic species presence often are low in such springs, with all but the latter increasing over distance downstream through the springbrook (e.g., Glazier, 2014). Thus, considerable ecological variance exists in relation to shading as well as other constraints on productivity. Conceptual modeling of those differences in the context of subsidy exchange can provide the foundation for future study and predictive modeling.

Humans and Springs

Uses

Anthropogenic preemption of ecosystem goods and services, and well as regional and global environmental alteration can alter all of the above hydrogeological, climatic, and ecological characteristics and processes of springs, resetting the ecosystem trajectory of ecosystem development (Fig. 1). Human evolution is uniquely tied to springs, as demonstrated in the paleohydrological reconstruction of the Olduvai Gorge in Kenya (Cuthbert and Ashley, 2014). During times of drought, early hominins there likely retreated to springs, which served as refugia buffered to some extent from climate change. However, springs also serve as ecological ambush sites for both human and non-human predators, which may account for the association of human remains with those paleosprings, and Pleistocene megafaunal kill sites at North American springs (e.g., Haynes, 2008). However, and perhaps due to the high rates of organic production and decomposition, there appears to be a general paucity of fossil remains from paleosprings prior to the Neogene.

Springs have been widely and actively used, and revered by humans throughout recent pre-historic and historic time. The Greek Oracle Springs at Delphi played a central role in world politics for nearly a millennium (Broad, 2006), and Peirene Fountain in Corinth was used for several thousand years for religious purposes and therapy (Robinson, 2011). Gihon Springs in Jerusalem, the many springs described by Pliny the Elder, European springs appropriated for Roman aqueducts, and many more examples exist of springs being intensively used by humans throughout history (e.g., Kreamer et al., 2015). In arid North America, multiple indigenous tribes regard individual springs as the place of emergence of their culture, including the Hopi Sipapu, the Zuni Ribbon Falls Springs, the Hualapai Peach Springs in the Southwest, and Gabrielino Tongva (Kuruvungna) Springs in Los Angeles, California, and others. Nabhan (2008) and Rea (2008), and other authors document indigenous reverence for and use of springs.

Unfortunately, for all the reverence in which they are held, springs stewardship has remained remarkably under-informed. In recent times, the intensification of appropriation of springs ecosystem goods and services has accelerated to the point that springs and springs-dependent species in many regions are threatened by both regional and local human activities. Groundwater depletion is a major, coarse-scale threat to the continued existence of springs in many developing regions, particularly where there is little concern for, or regulation of groundwater extraction. Such regulation is regarded as a states' right issue in the United States, and has contributed to the overdraft or dewatering of many large, important aquifers, such as those around large southwestern US cities like Las Vegas (Deacon et al., 2007), and the Ogallala Aquifer in the central southern Great Plains (McGuire, 2007). In addition, widespread contamination of groundwater may occur through hydraulic fracturing (e.g., Burton et al., 2016). More localized threats include: geomorphic alteration or obliteration of springs sources through agricultural and livestock management practices; spring box housing required by the US Environmental Protection Agency to protect drinking water sources; surface water pollution by livestock; inappropriate fencing; single-species management efforts; alteration of adjacent landscapes (e.g., upland grazing or forest management; flow regulation of rheocrene springs on river floodplains, etc.); as well as many other impacts. Specific springs types, such as southwestern ciénegas have a lengthy history of appropriation, loss and impairment, making them now among the rarest springs types in the American Southwest (e.g., Hendrickson and Minckley, 1985). However, not all anthropogenic impacts on springs negatively affect ecological properties. For example, Zawal et al. (2018) reported that flow regulation of Krąpiel River in Poland prevented flood scour of floodplain springs and enhanced the diversity of springs-dependent mites and other invertebrates.

Few regional studies of springs economics have been conducted, but those that have indicate that springs can have enormous impacts on local economies and societal well-being (e.g., Griebler and Avramov, 2015; Mueller et al., 2017). Gleick (2010) emphasized that water bottling operations also have become a multi-billion dollar worldwide industry that is having severe impacts on groundwater supplies.

Springs Ecosystem Conservation

Springs and the aquifers that support them are globally threatened by human activities, and many recently reported extinctions have been of springs-dependent species. Groundwater pumping, livestock and other agricultural uses and pollution, mining impacts, urbanization, and the introduction of non-native species have altered many springs on Earth, and nearly 20% of submarine springs appear to be threatened by sea-floor mining. The extent of ecological impairment of springs often exceeds 70% among many landscapes in Europe, North and Central America, and Australia, and urbanization of arid regions often depletes local groundwater, eliminating springs altogether. Nearly every study of springs ecosystems indicates the need for better conservation of springs and springs-dependent species (e.g., Minckley and Deacon, 1991). However, the only springs type currently recognized by the European Union (2014) as worthy of conservation are petrifying springs (Cantonati et al., 2016), and only a few countries in the world have national springs protection programs. Given the great biological, cultural, and socioeconomic value of springs, and the crucial role of sustainable groundwater for continued human existence, springs warrant far more conservation attention than they previously have received (Cantonati et al., 2020).

Several organizations have begun to promote improved springs management, among which are the US Forest Service (2012), the Howard T. Odum Florida Springs Institute (floridaspringsinstitute.org), and the Museum of Northern Arizona Springs Stewardship Institute (SSI) in Flagstaff, Arizona (<http://SpringStewardshipInstitute.org>, <http://SpringsData.org>; Ledbetter et al., 2014). The missions of the latter two organizations are to improve scientific understanding and management of springs in Florida and throughout the world, respectively. SSI provides protocols, free on-line information and education on management through trainings in springs inventory, ecological assessment, information management, planning, implementation, and monitoring.

If the supporting aquifer is relatively intact and functioning, aridland springs ecosystem rehabilitation efforts can be highly successful (Davis et al., 2011; Lehosmaa et al., 2017). For example, Burke et al. (2015) documented a well-planned restoration plan for Pakoon Ranch Springs in northwestern Arizona, and over a five-year period transformed a heavily degraded former cattle and ostrich ranch into a well-functioning restored springs complex. Cole and Cole (2015) reviewed the distribution and status of aridland ciénegas, recommending rehabilitation actions for stewards of those springs. Rehabilitation recommendations multiple springs types are presented in Stevens et al. (2016c), who conclude that best management practices for springs often can easily and inexpensively be successful, even on severely degraded springs, provided the aquifer is at least moderately intact. Among the actions, simple rehabilitation actions can include: protection of the often biologically distinctive source area by fencing; installation of a flow splitter to provide water for human uses while still maintaining flow at the source; and constructing a trail to the source to reduce hillslope erosion (Stevens and Meretsky, 2008).

Conclusions

I describe and discuss the global springs biome, including conceptual, physical, biological, ecosystem ecology, and anthropogenic interactions, and I distinguish, where relevant, differences between aridland springs and those in humid regions. The background literature and information presented indicate that springs in both aridlands and mesic environments broadly overlap in ecosystem characteristics and processes. However, aridland springs differentially or more often appear to have: (1) steeper environmental gradients of moisture and nutrient availability between the springs and the adjacent uplands habitats, creating (2) more discrete and distinctively different assemblages; (3) higher levels of endemism and rare species occurrences, with some springs functioning as evolutionarily significant paleorefugia; (4) interrupted, losing-stream springbrook habitat disconnectivity, which may thwart or delay colonization by aquatic non-native species; (5) a tendency towards lower levels of flow, with an increased propensity for ephemeral flow; (6) reduced resiliency and a tendency towards more dynamism in vegetation development, and likely faunal assemblage development, following disturbance; (7) greater susceptibility to anthropogenic impacts, particularly appropriation of water resources, and (8) consequent loss of springs habitat and increased probability and incidence of extinction of springs-dependent species.

With their diverse geomorphology, ecology, and biotic assemblages, springs ecosystems constitute a distinctive global biome, one that differs strongly in physical derivation, ecological processes, and assemblage composition from those in immediately adjacent uplands. Where the springs biome exists in arid lands, it becomes highly distinctive and critically important, providing point source biodiversity and ecological, cultural and socio-economic influence and interactivity. The sensitivity of aridland springs to anthropogenic alteration cannot be overstated, making them the “canary’s canary in the coal mine,” and whose degraded ecological condition portends long-term threats to groundwater supplies and quality, landscape ecological integrity, and societal sustainability.

The loss and impairment of springs ecosystems constitutes a global crisis that, despite much recent research, is still and ever more rapidly increasing in severity. Averting this crisis requires scientific agreement about the springs lexicon and classification (Thompson et al., 2002; Stevens et al., *in press*), as well as far more public discussion, support and political will to invest in basic mapping, inventory and status evaluation, and implementation of often simple, inexpensive rehabilitation measures. Although environmental foresight has yet to become a conspicuous trait of human society, more education and outreach is needed to shift cultural perceptions and improve environmental stewardship. Such a paradigm transition is desperately needed to reduce our impacts to these remarkable, irreplaceable ecosystems. The global demise of springs is a challenge humanity can overcome if only we can muster the individual and collective societal will to do so.

Acknowledgments

I thank the Museum of Northern Arizona (MNA) and its administrative staff for support of my work. I thank Marco Cantonati, Rod Fensham, Doug Glazier, Robert Knight, Don Sada, Ed Schenk, and Abe Springer for conceptual discussions on springs ecosystem ecohydrology. The MNA Springs Stewardship Institute staff provided much-appreciated assistance in information management and map production, particularly Jeri Ledbetter, Marguerite Henrie, and Jeff Jenness. I thank the *World Biomes* editor and anonymous reviewers for insightful and much-appreciated comments on earlier versions of the text.

Abstract

Headwater streams are the source streams at the initiation points of all river networks. These source streams may make up almost 80% of total stream length, but because of their small size and water volumes are extremely sensitive to the surrounding landscapes. Headwaters contribute to the characteristics of the downstream network in terms of water quality (nutrients, other solutes and temperature), sediment transport, and organic matter supply. These streams represent a distinct ecosystem as they support organisms that require relatively constant physical conditions, enemy-free spaces, or specific resources typical of source streams. The species found there are often unique to headwaters, and the key ecosystem functions usually differ from downstream in terms of being more dependent on organic matter sources from the surrounding terrestrial landscape, rather than instream primary production. Headwaters are also very sensitive to land use as they are strongly regulated by their surroundings, and often not protected.

Introduction

In common language, headwaters may refer to all source waters upstream of the point at which the observer is standing, meaning it could be an enormous area contributing to the flow at a given point. However, in the scientific literature headwaters are the smallest of what we consider small streams, that is the most headward of channels, but there is no consensus on a definition. Definitions based on stream order are problematic as the order system is typically based on a 1:50000 (Strahler, 1952) or 1:100,000 map scale, and even "first order" streams (first blue lines on such a map) could be relatively large at that scale. Meyer et al. (2007), Wohl (2017) and others define headwaters as first- and second-order streams, and Meyer et al. (2007) specifies a 1:24000 scale, which is still potentially large. We define headwaters as those streams without perennial tributaries, distinguishing them from other small streams (Gomi et al., 2002; Moore and Richardson, 2003; Richardson, 2019). That is, in the context of a network, they are the uppermost link with no other links (branches) until the node (tributary junction) at the base of the headwater. Another way of defining headwater streams is the intensity of the interaction between the stream and its surrounding landscape, i.e. the degree of coupling, which is difficult to measure (Church, 2015). One approach to this is whether coupled hillslope-stream processes, such as mass-movement, dominates sediment supply (Gomi et al., 2002). Hence, definitions differ across the literature. Our definition is based on headwaters being first-order streams based on field observations, which we have tried to differentiate from other small streams (second order and higher). Headwater streams can be ephemeral, intermittent or perennial (Feminella, 1996), and may even change between these classes from year-to-year based on precipitation patterns in any year. Regardless of a firm definition, they are the smallest of streams in a river network.

Leopold et al. (1964) estimated at least 73% of stream channel length in fluvial networks are 1st and 2nd order streams based on 1:24000 scale maps. Some estimates suggest that only 21% (Hansen, 2001) to 43% (Meyer and Wallace, 2001) of actual stream channel lengths even show up on the map scale of 1:24000. Hence, however headwaters are defined, they likely account for much more stream length than other channel sizes in any river network.

Initiation points of streams occur at the point of concentrated water flow leading to clear evidence of fluvial processes, such as sediment movements (Montgomery and Dietrich, 1992). Headwaters may also originate from glaciers, snow packs, springs, or other sources. In some cases the first stream in a network might be from a wetland or lake, and this may be considered a headwater by some scientists.

Headwaters can occur anywhere that surface flow is initiated from alpine areas to sea level, and in rainforests through to prairies and near desert. Thus, many of their properties will be very dependent on the nature of the watershed they drain, including climate, vegetation, geology and hydrology.

Given that headwaters typically drain small areas, they can be sensitive to periods of low precipitation inputs and gradually diminished flows that in some years may leave them without visible surface water for periods of time. The loss of surface flow may begin at the initiation point, or further downstream, which is often referred to as the variable source area concept, but there may be other variants on how types of source areas for flow actually influence discharge (e.g. [Dahlke et al., 2012](#)).

Properties of Headwaters

Hydrology

Headwaters gather water from a relatively small contributing area or catchment, and thus they can be individually quite “flashy”, i.e. instantaneous stream discharge can change quickly. Some estimates of the contribution of headwaters to the mean annual flow of entire river networks are ~41% for a drainage in Colorado ([Caruso and Haynes, 2011](#)) to ~70% in the northeastern USA ([Alexander et al., 2007](#)). However, as small systems, the peak discharges may still be relatively small. Their small catchment areas also often mean that there is limited groundwater storage and at times of year surface flow may retreat to a few lengths of contributing area, that is, they have a variable source area. These periods of low flows can be a strong influence on the biology as water availability disappears from the surface and any moisture may be subsurface, that is, hyporheic. Many headwater streams go through periods when surface flows disappear and they become intermittent annually or during years of lower than average precipitation ([Fig. 1](#)).

The discharge rates of headwaters can be highly variable across the landscape and through time in terms of discharge at any given moment due to the variation in inputs of precipitation, storage capacity, and the flowpaths through which shallow groundwater moves. The timing of discharge depends on when precipitation arrives, and in what form, as snow storage can result in low winter discharge coupled with a spring freshet as snow melts. In some regions, rain-on-snow events result in large peak flows as the input of warmer rain adds melted snow to the discharge generation (e.g. [Moore and Wondzell, 2005](#)). The relation between precipitation and discharge also depends on the characteristics of the soils and geology of the shallow groundwater zone, where coarse soils in glaciated or volcanic landscapes may be highly permeable, whereas clays may be more slowly draining, or even lead to overland flows. The storage capacity of headwater basins can be overwhelmed if the antecedent conditions leads to saturated soils and precipitation flows directly into streams, often leading to greater peak flows during periods of regular and intense precipitation.

Geomorphology

In some landscapes with large parent materials in the soils, headwaters may be colluvial ([Montgomery and Buffington, 1997](#)), i.e. their peak flows are unable to move the largest particles, and the channel works its way around those larger rocks and pieces of wood. As headwaters are usually directly connected to the hillslopes and there is no stored alluvium or floodplain, therefore slope failures often end in the channel. Much of the sediment supply entering stream networks comes from mass wasting events along the hillslopes connected to headwaters, as well as from erosion of slopes and streambanks.

Headwaters are sometimes steeper than downstream reaches, but this is not necessarily so. [Church \(2015\)](#) suggests that volume and timing of discharge, sediment caliber and volume, the bank (including slope of the bank) and bed structures, and channel gradient are four of the dominant processes influencing morphology of headwater streams. This influences structure as fine-grained materials can be easily moved by most flows, deposited on the banks, and deeply rooted, riparian vegetation can strongly influence structure and lead to deep, narrow channels. However, in very low-gradient channels, even this bed material may remain dominant ([Church, 2015](#)). Headwaters can express step-pool morphologies when the caliber of bed materials are large and channels are steep, through to deeper, meandering channels when finer materials dominate the sediment supply in lower gradient channels. Nevertheless, the majority of high roughness channels in a network are headwaters ([Church, 2015](#)).

Headwaters are often the source of sediment supplies to downstream, shaping the possible configurations of downstream channel structures ([Church, 2015](#)), depending in part on the transport capacity of the source streams, grain-size distributions and slopes, as above. The balance of sediment supply and transport are dynamic, and vary through time and space, creating heterogeneity in morphology and rates of transport downstream (e.g. [Fritz et al., 2018](#)). Large wood can be important as a channel-structuring element ([Gomi and Sidle, 2003](#)), but often spans headwater channels for a considerable period before falling into the channel when it is in advanced states of decomposition and more easily broken and transported.

Water Chemistry

Inputs of water are characteristic of shallow groundwater and precipitation, and thus water chemistry bears a signature of local groundwater inputs. Often it is suggested that headwater streams are relatively nutrient poor, as it depends on the subsurface, geological composition through which groundwater flows, and also the residence time of the water. Some transformations, e.g. nitrogen and other solutes, can occur at higher rates in headwaters than larger streams and thereby reduce the nitrogen concentrations delivered downstream ([Peterson et al., 2001](#)). One estimate suggests 65% of nitrogen flux to downstream networks comes from headwaters ([Alexander et al., 2007](#)).

Fig. 1 Three examples of headwater streams. (A) A headwater stream in New Zealand's south island, showing a step-pool morphology as can occur in steeper landscapes with large rock elements. (B) A headwater in a boreal forest in Finland. (C) A headwater in the tundra-like landscape of western Iceland.

Influence of Surroundings on Local Stream Properties

The very high ratio of edge to area in headwaters means that streamsidelines have a very large influence on these small streams, through shading, inputs of organic matter (e.g. leaves, wood, seeds), etc. As stream width increases, the amount of organic matter inputs per unit area, particularly leaf litter, decrease, so the surrounding vegetation has less and less influence (e.g. [Naiman and Sedell, 1979](#)). Headwater streams are often heavily shaded, but that depends on the nature of the surrounding vegetation and the local topography. Forest streams are typically shaded, but in low-relief landscapes, the water table may restrict forest trees and support shrub and herb-level vegetation, such as willows and sedges, which offer little shade. Likewise, headwaters in prairie or alpine situations are unlikely to be shaded by vegetation to any great extent.

The pattern of shading of headwaters by forests depends on the successional state of the forest (more, but patchy, light through older forests), and some amount of patchy light may contribute to the overall productivity of a stream ([Heaston et al., 2018](#)). The

surrounding riparian forest can also have a large influence on flows during low-flow periods as vegetation may extract water for transpiration from subsurface (e.g. [Moore and Wondzell, 2005](#)).

Disturbance Regimes

Headwaters experience a number of disturbance regimes. Often these disturbances are intense, but infrequent, such as mass wasting events that accompany high precipitation events. Wet soils can lead to slope failures which run into headwaters. Moreover, sediments (rock and wood) stored in headwaters can be mobilized during higher flows and lead to debris torrents of materials down the small channels to where the material is deposited where gradients are lower (creating fans) or continues down larger streams into which materials are delivered. Examples of such events have been described for streams in Oregon (e.g. [Lamberti et al., 1991](#); [Swanson et al., 1998](#)).

Headwaters are also subject to the impacts of fire, volcanic eruptions, etc. [Nitschke \(2005\)](#) compared the impacts of fire on headwater streams to that of forest harvesting, and found fire resulted in larger increases in nutrient and other solute fluxes, increased sedimentation, and lower concentrations of dissolved organic carbon than occurred following forest harvesting.

Food Resources

Biologically available energy sources (resources at the base of headwater communities) are often divided into green (primary production) and brown (detrital) pathways, that is, autotrophic and heterotrophic production, respectively. Headwaters are often heterotrophic in forested settings, such that inputs of organic matter from vegetation contribute the largest fraction of available energy for stream organisms (e.g. [Fisher and Likens, 1973](#)). This, coupled with shading that can limit primary production, means that allochthonous (from outside the stream) sources provide most of the biologically available energy. However, headwaters can arise in any landscape and the dependence on organic matter from vegetation may not be true in alpine, tundra and prairie regions.

Organic materials occur in headwaters in two primary forms, particulate and dissolved. Dissolved organic carbon (DOC) is not strictly speaking dissolved, as it is operationally defined as carbon-based molecules passing through a standard filter paper with nominal pore size of $\sim 0.7 \mu\text{m}$. DOC is typically available to bacteria that can use it as an energy source. Particulate organic carbon (also referred to as detritus) is divided into coarse ($> 1 \text{ mm}$ diameter) and fine ($< 1 \text{ mm}$ diameter, but larger than DOC), largely as coarser particles are decomposed more commonly by fungi and smaller particles processed by bacteria. The size of these particles also influence which consumers eat the particles and associated microbes. DOC enters headwaters in groundwater, and also from the leaching of soluble organic compounds from particulates, which are primarily delivered from vegetation, such as leaf litter and wood, in the area surrounding headwater streams.

Organic matter inputs occur seasonally and can lead to periods of limiting supply for consumer populations in headwaters (e.g. [Richardson, 1991](#); [Wallace et al., 1999](#)). The nutritional quality of organic matter depends on the species, lignin content (e.g. wood is a low-quality resource compared to leaves), and nutrient regime (e.g. [Rosemond et al., 2015](#)). Other organic inputs include terrestrial invertebrates from the surrounding vegetation, which can contribute considerably to the production of small fishes and other predators (e.g. [Wipfli, 1997](#); [Sato et al., 2016](#)).

Autochthonous (primary) production can include photosynthesis by algae (including cyanobacteria), which contribute to biofilms growing on most surfaces (rock, wood, invertebrates, other plants, etc.). Mosses can also be significant contributors to primary production in headwater streams ([Fritz et al., 2009](#)). Infrequently, in headwaters draining iron-rich geologies the growth of iron-reducing bacteria can contribute to biofilm production in small streams as an additional source of biologically available basal resources (e.g. [Hildrew and Townsend, 1976](#)).

Biological Diversity

Reviews on the biological diversity of headwaters have been published by [Meyer et al. \(2007\)](#), [Richardson and Danehy \(2007\)](#), and [Richardson \(2019\)](#). Headwaters are key habitats to many organisms, some of which are found nowhere else in stream networks. Some of the reasons for these organisms to use headwaters are summarized in [Table 1](#). However, the relative importance of some of these functions are yet to be tested, as one requires well-designed experiments to separate the individual contributions of each of these processes.

Many species depend on particulate organic matter as a food source, and these organisms are referred to as detritivores, or by a description of the way they eat, known as functional feeding groups ([Cummins, 1974](#)). Species feeding on large particles are often known as shredders as they break down larger particles, and species feeding on fine particles are called collectors, which can be further broken down into filterers (some kind of filtering mechanism to catch particles) or gatherers (collect particles from the stream bottom). Detritivores, particularly shredders, are frequently more abundant in headwater streams than in larger streams as a consequence of the abundance of these inputs. However, it is clear that this is not globally the case and in many tropical streams there may not be specialist detritivores as there are in more temperate and subtropical systems. This dependence on coarse particulate organic carbon is one reason for species to be found primarily or exclusively in headwater streams.

Given their small size, headwaters rarely support larger-bodied predators, or only small numbers. This provides other species with a refuge from larger-bodied predators. In many cases the top predators might be small fish or amphibians. Some species appear

Table 1 Some of the putative mechanisms for the particular use of headwaters by species.

Mechanism	Explanation
Dependence on organic matter	Often shaded by vegetation, which contributes organic matter and limits primary production. Dependence on groundwater inputs also leads to higher concentrations of dissolved organic carbon contributing to microbial growth
Thermal conditions	Groundwater inputs tend to predominate flow generation and results in moderated temperature regimes
Enemy-free space	In headwaters the small spaces do not support many or any larger predatory species, and thereby provides a refuge for some species
Reduced competition	Some species find relaxation of competitive interactions in headwaters
Breeding and rearing	This may entail some degree of predator avoidance or other specific resources
Flow conditions	Discharge can be very “flashy”, i.e. rapid responses to precipitation. Discharge can also be very low due to small contributing areas during times of limited precipitation
Water quality	Often considered to be nutrient poor, and reflects the signal of the groundwater that contributes to flow
Physical structure and size	Small habitat spaces restrict potential for large-bodied species, limits population sizes for other species. Often colluvial, depending on geology and gradient
Disturbance regimes	In some landscapes, channelized debris flows may be rare but large magnitude. Punctuated changes in discharge due to large inputs can lead to flood disturbance. Fire and drought can also be important disturbance events

This table builds on summaries in Meyer et al. (2007), Richardson and Danehy (2007), and Richardson (2019).

to use headwaters seasonally for particular life stages, especially for young (small) individuals avoiding predators. Seasonal use of headwaters might also provide for use of a thermal preference for a narrow range of temperatures.

There are many species found in headwaters. The best studied headwater stream in the world is arguably the Breitenbach in Germany in which over 1800 species have been found, including over 1000 insect species (Wagner et al., 2011). Other studies in headwaters have documented similar levels of diversity in subsets of taxonomic groups, i.e. characterization of invertebrates or algae, but not the entire community. The diversity of headwater communities includes all kingdoms of life. The best characterized groups are the animals, algae, and fungi. Even some invertebrate groups may be less well known, such as Nematoda (Majdi and Traunsperger, 2015). Protists, bacteria, and viruses are probably more speciose than currently understood and there is a great opportunity to add to knowledge of these groups in headwaters.

Ecosystem Processes

As the first channels in a stream network, headwaters are at the endpoints and have only one connection to the rest of the network, in contrast to larger streams which have many nodes connecting them. Fagan (2002) has demonstrated how this is likely to influence local population dynamics in headwaters where isolation by distance along the stream network, as well as the relatively small habitats they provide results in low colonization rates to headwaters. Moreover, the small spaces of headwaters also implies relatively small populations, with a higher potential rate of local extinction (population extinction at a site). The balance of colonization relative to extinction also imply headwater populations are more vulnerable to disturbance than species that also occur in larger streams (Fagan, 2002). This also suggests that headwater communities operate as meta-communities, linked by colonization, even if the rates of colonization might be low (Datry et al., 2017). Given that materials, nutrients and organisms potentially move between adjacent and downstream ecosystems, headwaters function as meta-ecosystems (Datry et al., 2017; Harvey and Altermatt, 2019).

Headwater streams contribute to, and form, connections to downstream waters through supply of water, nutrients, other solutes, sediments (of a range of sizes), and biological materials (Fritz et al., 2018). These connections are critical to supplying organic materials to downstream in the form of particulate and dissolved carbon (Wipfli et al., 2007). Organic materials that fall into headwater streams are processed (i.e. broken down to smaller particles or incorporated into animal biomass) in situ or exported downstream (Webster et al., 1999). Headwaters are considered leaky ecosystems, and studies have demonstrated that most of the process of creating smaller, easily transported particles is done by invertebrates. For instance, when densities of invertebrates were reduced through insecticide application over 3 years, the flow of fine organic particles was reduced by ~56% relative to control streams (Wallace et al., 1991). In that study of three headwater streams in North Carolina, the average export of fine particles per year was in the range of 221 to 369 kg ash-free dry mass year⁻¹ (Wallace et al., 1991) to downstream reaches. Wipfli and Gregovich (2002) concluded that export of organic materials, including invertebrates, from headwaters could support a large portion of the fish production in the larger receiving streams.

Connectivity can be defined as the degree to which ecosystems functionally and structurally interact (Leibowitz et al., 2018), and headwaters are considered to be strongly connected to downstream reaches. Inputs to headwaters can also come from downstream and riparian areas, and this interconnectedness is referred to a meta-ecosystems to recognize the contributions of adjacent ecosystems (Datry et al., 2017).

Given the contributions of headwaters to water quality (e.g. solutes, temperature) and quantity, organic matter supplies, and value as habitats, it is evident that alterations to headwaters through disturbance and land use can have large cumulative effects.

However, the individual effects of modifications are hard to trace downstream, in part due to the dilution effects as networks increase in size (discharge) downstream.

Management and Threats

Small streams are easily threatened by land use, and often converted to ditches and buried in pipes to make way for development (Elmore and Kaushal, 2008). Developed landscapes have been referred to as “stream deserts” due to their lack of surface stream reaches due to stream burial in storm drain systems (Napieralski et al., 2015). Incorporation of headwater streams into pipes often leads to rapid downstream changes in discharge in response to precipitation given there is little resistance to flow movement through pipes, which can lead to downstream flooding where the storm drain system flows into larger streams. Burial of headwater streams also reduces nitrogen mineralization and leads to higher export rates of nitrogen to downstream areas contributing to additional eutrophication where drainage pipes drain to rivers (e.g. Peterson et al., 2001; Beaulieu et al., 2015). One of the most destructive of land-use impacts on headwater streams is associated with mountaintop mining, in which overburden is bulldozed directly into headwater streams, filling the valley and eliminating the stream (Palmer et al., 2010).

Forestry, agriculture, urbanization, and other land-uses can have profound impacts on headwater streams, even if they are not buried or channelized as mentioned above. In general, a suite of changes occurs that has been referred to as the urban stream syndrome for urban headwaters (Booth et al., 2016) and similarly for forestry landscapes (Richardson, 2008). These changes include higher peak flows (runoff over pavement, pipes or compressed soils, lack of uptake by vegetation), higher erosion and nutrient transport, warmer water in summer, and channel simplification. There can also be higher concentrations of contaminants such as pesticides and other organic compounds.

Legislative provisions for protection of headwaters is often lacking (Kuglerová et al., 2017). In the USA headwaters are a point of contention for whether the Clean Water Act applies (Fritz et al., 2009). Protection of headwaters from forestry activities varies from a great deal of protection in states like Washington (buffers at initiation points, junctions, upstream of extent of fish), to little more than a machine-free zone in adjacent British Columbia.

Although headwaters are rarely impounded for water supplies in most places, in regions with subsistence agriculture, even headwaters may provide irrigation and drinking water supplies. However, impoundments for power production, flood control, and other uses still impact headwater streams by flooding them and turning them into parts of the resulting reservoirs.

Stream restoration is a widespread practice in an attempt to repair damage due to past land use. Most of these activities are applied to streams larger than headwaters, and not particularly successfully (Palmer et al., 2014). However, in places efforts at bank stabilization, exclusion of livestock, and planting of riparian trees for shade have had success in bringing back some of the functions of headwater streams (Beechie et al., 2010). In some rare instances the loss of headwater streams is being reversed by a practice known as daylighting of buried streams, that is, returning them to surface flows (Wild et al., 2011).

Many streams around the world now receive some amount of streamside protection, but this is rarely the case for headwaters (Richardson et al., 2012). Streamside management often has the aim of providing shade, streambank stability to reduce erosion, nutrient uptake and organic matter inputs (including wood). This management often takes the form of leaving some amount of vegetation, a buffer, along streams. Buffers are now commonly applied in forestry, agriculture and urban settings (Richardson et al. 2012). The amount of vegetation retained varies considerably by jurisdiction and for the particular kind of land use (Blinn and Kilgore, 2001). Small streams may need forested buffers of 30 m or more to retain their functions in terms of erosion control and sediment storage, channel structure, temperature regimes, nutrient processing and community structure (Sweeney and Newbold, 2014). However, most headwaters are unlikely to receive anything close to this amount of protection from adjacent land use. Clearly, headwater streams deserve greater protection than currently afforded in most jurisdictions.

Headwater streams are increasingly recognized for the critical roles they play in contributing to productivity and integrity of downstream ecosystems (e.g. Nadeau and Rains, 2007; Colvin et al., 2019; Kuglerová et al., 2019). These functions include moderating peak flows and provision of cool, clean water. Intact headwaters also limit the degree of erosion which mitigates sediment supply to downstream. Headwaters also process organic matter and critically supply organic materials that support the productivity of downstream foodwebs (Wallace et al., 1991; Wipfli and Gregovich, 2002). Headwater streams can provide breeding and rearing sites for species that eventually form part of downstream biological communities. Nutrient mineralization in headwaters also reduces the potential nutrient supplies to downstream (Peterson et al., 2001). In fact, an extrapolation of estimates of some ecosystem services (water supply, water purification, and carbon sequestration) from headwater streams for the entire USA suggests headwaters may provide value of \$US 15.7 trillion per year (Nadeau and Rains, 2007; Hill et al., 2014; Creed et al., 2017). Headwaters serve a large role in determining the characteristics of downstream ecosystems, and those functions are easily disturbed by land use.

Abstract

A Habitat Status Assessment (HSA) was completed for streams, including rivers and seeps, for the state of Hawai'i. This stream HSA defines what Hawaiian streams are, what the ideal stream conditions were prior to human arrival, the current stream condition based on human and climatic stressors, and what streams may become from an analysis of four future scenarios. Hawai'i currently has 376 perennial streams and less than 15% of those streams are classified as pristine, typically having clear, cold water, and a strong flow all year round (U.S. Fish and Wildlife Service, 1978a,b). Rainfall is the primary source that feeds the streams from the headwaters beginning in the mountains and flowing toward the sea. With the lack of references and descriptions available, we are only able to infer how Hawaiian streams functioned under ideal conditions prior to human contact approximately 1500 years ago. Stream viability from pre-human contact to current condition was assessed based on the resiliency of a stream to withstand stochastic environmental events, redundancy to withstand a catastrophic event, and the representation of streams to adapt to a changing environment over time. Current condition of Hawai'i streams was assessed

from when the first Polynesians arrived up to 2018. Streams were important to Hawaiian Society as land divisions called Ahupua'a were established based on local watershed boundaries from mountains to the sea. Within each Ahupua'a, streams were utilized by Native Hawaiians for agriculture and aquaculture (CWRM, 1993). Presently, about 50% of all Hawaiian streams are diverted and highly altered through agricultural use and urban developments (U.S. Fish and Wildlife Service, 1978a,b; Oki, 2003). Hawaiian streams continue to degrade due to pressures from anthropogenic, stochastic, and climatic events. These include development, channelization, water diversion, human recreation, pollution, climatic events such as drought, erosion and sedimentation, and invasive species. Current conservation efforts for restoration and management, policy and laws, education and outreach, and creation of protected natural reserves are ongoing, and these efforts aid in continuing the protection of Hawaiian streams from further decline in functionality from listed stressors. This HSA for Hawaiian streams analyzed four future scenarios all differing in their levels of natural resource management from 2018 to the foreseeable future of 2035. The three variable conservation management parameters for each future scenario are conservation values, laws and biosecurity, and development or conservation planning. The four future scenarios analyzed for Hawaiian streams are status quo, slightly improved conservation measures, substantially decreased conservation measures, and substantially improved conservation measures which are all based on varying degrees of conservation management. Based on these analyses, we anticipate that stream habitats will continue to decline unless there is a significant increase in the conservation management parameters.

Introduction

The Hawaiian archipelago is the most isolated landmass in the world with extreme variations in elevation, wind, rain, topography, substrate, and hydrology. These variations coupled with the remoteness of the archipelago within the Pacific Ocean, create unique biomes on each of the islands and atolls. We provide an overview of the coastal system in Hawai'i and describe the ecological factors that have influenced the system over time and into the future. Please see the chapter by Harrington on the Physical Geography of the Hawaiian Islands included in this work for a full description of the unique geography, geology, climate, hydrology and descriptions of the islands in the Hawaiian archipelago.

Description

Perennial streams in Hawaii are characterized by clear, cold water, with strong flow all year long. Rainfall is the primary source of water for Hawai'i's streams, although snow melt may provide some minor contribution on the higher mountains. Once rain infiltrates into the soil, the water flows down slope below the surface, often resurfacing as an existing stream bed or by creating a headwater spring source for an entirely new stream. From the streams' headwaters in the rainforest and mountain zones, they flow toward the sea. During this travel, they carve gulches, gullies, and narrow canyons. They also flow over rocky cliffs creating waterfalls and can have sufficient velocity to move boulders and trees from their banks during storms. Farther downstream, these mountain streams can form canyons, valleys, and coastal floodplains (CWRM, 1993). The windward sides of islands are usually the wettest and contain the majority of perennial rainforest streams that support numerous aquatic flora and fauna (Parham et al., 2008). Many streams flow into valleys in the form of waterfalls. As a stream flows, softer material in a streambed erodes relatively quickly until a harder substrate is reached. The stream will continue to flow across this substrate until it reaches and flows over an exposed edge, creating a waterfall. The softer material beneath the falling water continues to erode away until the harder substrate is exposed, and the process is repeated. Sometimes a deep plunge pool is formed where the falling water meets the substrate. These pools often can't be seen from the bottom of the valley (Ziegler, 2002).

Only five of the Hawaiian islands (Kaua'i, O'ahu, Moloka'i, Maui, and Hawai'i) have enough elevation to capture the rain clouds brought to the islands by the prevailing trade winds, and for the resulting orographic rainfall to generate perennial streams. Ni'ihau and Lāna'i are lower in elevation and have ephemeral streams, meaning they are intermittent and may only occur following large rain events. Kaho'olawe, Nihoa, Mokumanamana, Mokupapapa, and Puhahonu are lower and only have seeps (a small leak or flow through porous material or small holes) and ephemeral seeps (a seep that only leaks/flows during and following a period of heavy rainfall).

Hawaiian streams generally are defined by the following characteristics:

1. They are small in length compared to many of the larger streams on the United States mainland. Only 28%, or 7.4%, of the streams in Hawai'i are 10 miles or longer (DAR Hawaiian Streams, 2018a). Larger streams are typically called rivers. The Wailuku River on the island of Hawai'i is 28 miles long and is the longest river in Hawai'i.
2. Many Hawaiian streams are characterized by waterfalls. This feature is due to the steep profile of Hawai'i's mountains, which are composed of successive layers of lava with varying hardness, and is especially evident in the geologically younger islands, such as the island of Hawai'i.
3. Rainfall is the primary water source for stream habitats. Localized heavy rainfall and storms may cause flooding. These flood events, often lasting only a couple of days contribute to the flashy (as in flash flood) discharge patterns characteristic of Hawaiian streams (DAR Hawaiian Streams, 2018a). Streams in Hawai'i are prone to flash floods because rainfall is intense, drainage basins are small, basins and stream profiles are steep, and channel storage is limited (Oki, 2003).

- a. Storm events passing through the islands are especially important in regard to generating runoff on islands of lower elevation, since such islands are unable to capture orographic rainfall. As such, the major surface water features on lower elevation islands are seeps and ephemeral seeps. These stream habitats heavily rely on storms passing through the Hawaiian islands for groundwater recharge. Without heavy rain events, seeps would dry out (Figs. 1–4).

Geology and Water Availability

The form and functions of Hawai'i's streams are created and maintained through frequent high flow events. However, low-flow and base-flow events are equally important, especially during periods of drought. Rivers, streams, and seeps fed by basal ground water exhibit permanent, stable low flows (U.S. Fish and Wildlife Service, 2010).

Fig. 1 Map displaying stream habitat for Island of Hawai'i.

Fig. 2 Map displaying stream habitat for islands of Moloka'i, Lāna'i, Maui and Kaho'olawe.

Streams in Hawai'i gain water along some reaches and lose water along other reaches depending on local geohydrologic conditions. Some streams can lose water if the streambed is above the water table in an area, while others do not flow continuously to the coast because water enters through the streambed and becomes groundwater. The hydraulic properties of the rocks near the stream affect the rate of flow between the stream and groundwater body. When stream channels are lined with concrete to channelize the water to certain areas, this makes it almost impossible for surface water to percolate through and add to the underlying groundwater levels (Oki, 2003).

The upper reaches of many Hawaiian streams are within or near the area where volcanic dikes crop out. Factors that affect water levels in streams and groundwater bodies can control the interaction between surface water and groundwater. These factors include rainfall, groundwater withdrawals, and ocean tides. Rainfall may cause dry, intermittent streams to flow, which can lead to discharge from a stream to the groundwater body or to the ocean. Long periods of rainfall may lead to increased groundwater recharge over a region and a rise in groundwater levels. Rising groundwater levels may lead to increased groundwater discharge to streams or reduced surface-water discharge to the groundwater body. At lower elevations, water levels in streams and groundwater bodies may be affected by ocean tides. Thus, streams in coastal areas may either gain or lose water during the day depending on the effects of the tides on streams and groundwater levels (Oki, 2003).

Natural and Physical Boundaries

A reach classification system (Parham, 2008) was developed by Bishop Museum researchers in collaboration with the State of Hawai'i's Division of Aquatic Resources (DAR) biologists to provide a general classification of stream reaches that could be applied systematically to all streams on all islands. The reach types are based on elevation and the presence and size of waterfalls in the stream.

- *Estuary*: All stream segments between the coastline and 3 feet (ft) (1 meter (m)) elevation.
- *Lower reach*: Stream segments lying between 3 ft. (1 m) and 65 ft. (20 m) elevation and below any barrier of at least 32 ft. (10 m) high.

Fig. 3 Map displaying stream habitat for Island of O'ahu.

- *Middle reach*: Stream segments lying at greater than 65 ft. (20 m) elevation or above the first 32 ft. (10 m) barrier and less than 656 ft. (200 m) elevation or below the first 65 ft. (20 m) high barrier.
- *Upper reach*: Stream segments lying at greater than 656 ft. (200 m) elevation or above the first 65 ft. (20 m) barrier and less than 2460 ft. (750 m) elevation.
- *Headwaters*: Stream segments lying at greater than 2460 ft. (750 m) elevation.

Biotic Components

In strongly flowing streams, there is little accumulation of sediment, leaf litter, and other loose debris due to continuous flow and flash flooding caused by heavy rains in the mountains or strong weather fronts. Storms can occur any time of the year but are most frequent during the winter months between February and April (Fitzsimons et al., 2008). Because of frequent flash floods, mountain streams remain in a constant state of recovery from the most recent freshet.

Flash floods flush away debris that contribute to oxygen depletion during periods of low water, remove sediments that can smother the eggs of stream animals, and open up the stream mouth where it flows into the sea (DAR Geology, 2018b).

Vegetation Composition and Structure

Generally, streams contain less than 25% canopy cover. Streams can flow through varied landscapes including rainforests, deciduous forests, and high altitude grasslands. Canopy cover is important because it keeps water cool and limits the growth of algae. Cool water has a greater oxygen holding capacity than does warm water. Streams without canopy cover are exposed to the warming effects of the sun, which can change plant and animal species composition and abundance. Streams that are exposed to too much sunlight may have thick algae attached to the rocks, floating algal mats, surface scum, and/or a microbial sheen. These are all

Fig. 4 Map displaying stream habitat for islands of Ni'ihau and Kaua'i.

indicators of eutrophication, an excessive richness of nutrients due to runoff which causes a dense growth of aquatic plant life (Natural Resources Conservation Service, 2001).

Habitat Viability

Resiliency (the ability to withstand environmental stochasticity), redundancy (the ability to withstand catastrophic events), and representation (the ability to adapt to a changing environment over time) will be discussed in the following sections as to how viable stream habitats were/are/expected to be (historically, currently, and in the future).

Prehuman Condition

Prior to the arrival of Polynesians approximately 1500 years ago, streams in the Hawaiian archipelago likely looked much different than they do today. Although no references or descriptions are available for this prehuman time period, we can infer what it may have looked like from existing stream systems and our knowledge of the ecological processes that affect stream form and function.

Prior to human arrival, we can assume that Hawaiian streams functioned under ideal conditions. The Natural Resources Conservation Service has described what ideal stream conditions might look like (Natural Resources Conservation Service, 2001).

Mixed (Open and Closed) Canopy

Canopy is an indicator of shade. Considering prehuman conditions involved no invasive plant or animal species, it is likely that canopy conditions let enough sunlight in for some algal growth that fed native aquatic species, but not enough to make the stream eutrophic. A mixed canopy increases the resiliency of the stream habitat by keeping the water cool during periods of drought, and by keeping the surrounding soil moist which reduces erosion.

Riparian Zones and High Bank Stability

Riparian area is the width of the natural vegetation zone from the edge of the active channel (or normal water line) out onto the floodplain. Considering prehuman conditions involved optimal canopy, and diverse understory, shrub, and groundcover species, it is likely that riparian zone conditions were good. A good riparian zone has high resiliency—reduces surface runoff, controls erosion, provides shade, and dissipates energy during flood events. Bank stability is the potential for erosion from the stream banks into the stream. High bank stability indicates the bank is not bare or erodible. Although, some bank erosion is normal in a healthy stream. Excessive bank erosion occurs where riparian zones are degraded. Considering prehuman conditions involved good riparian zones, it is likely that most stream banks were highly stable.

Low Turbidity

Turbidity is an indicator of erosion. Considering prehuman conditions involved optimal canopy, good riparian zones, high bank stability, and no invasive ungulates, it is likely that most streams were minimally turbid (because of high resiliency). In the rare event of flooding, it is likely that a stream habitat would become turbid for a short period of time, but would likely recover quickly once the surrounding riparian/bank area stabilizes. This high redundancy is attributed to rainfall. Surrounding riparian/bank areas on the windward side of higher islands were more redundant than those on the leeward side of lower islands because higher rainfall would help to regenerate vegetation and stabilize banks, which would in turn, limit erosion.

Low Plant Growth

Plant growth is an indicator of eutrophication. Considering prehuman conditions likely involved mostly shaded, nonturbid conditions, it is also likely that few streams were ever eutrophic. In the rare even of a fire, where surrounding vegetation and canopy cover were destroyed, it is possible that a stream habitat would experience higher than average plant growth because of over exposure to the sun. However, on higher islands that generate orographic rainfall, riparian vegetation and canopy would reestablish and prevent the stream from eutrophication. Stream habitats on higher islands are more likely to exhibit this type of redundancy than lower islands because of their ability to generate orographic rainfall.

Habitat Available for Native Species

The potential for stream biota to live, thrive, and recover from disturbance is dependent on the variety and abundance of suitable habitat available. Stream habitats on windward sides of higher islands were more likely to have higher representation than stream habitats on leeward sides of high and low islands because of the ability to generate orographic rainfall on windward sides. Considering prehuman conditions didn't involve stream alterations such as diversions, withdrawals, or channelization, it is likely that most of the larger streams on the windward sides of higher islands contained five main habitat types (streams on windward sides of lower islands possibly had five main habitat types, but they probably had less diversity):

1. *Seeps and springs*—Areas in the riparian zone where there is groundwater input.
2. *Pools*—Areas characterized by smooth undisturbed surface, slow current, and deep water. Included in this habitat would be deep plunge pools at the bases of cascades or waterfalls.
3. *Runs*—Areas characterized by moving water, but no broken water surface or whitewater.
4. *Riffles*—Areas characterized by broken water surface, rocky or firm substrate, moderate or swift current, and relatively shallow depth (less than 18 in.). Generally, the flow is fast and shallow.
5. *Cascades*—Waterfalls, or steep riffles with greater than 3% gradient.

Habitat Viability

Prior to human contact stream habitat likely exhibited high resiliency. For example, in the event of drought, there was likely enough canopy to keep the water cool and keep it from evaporating quickly. Similarly, the canopy was likely able to keep the soil in the riparian and buffer zones moist enough to support vegetation and prevent excessive erosion. In the event of lava, streams likely rerouted around the flow (or over time, over or through the lava rock, depending on how big the flow was). In the event of fire, if riparian vegetation was affected, the stream would likely have been susceptible to erosion until the vegetation was reestablished. However, since surrounding riparian habitat likely had high representation, affected areas would have been able to be reestablished relatively quickly due to the proximity of appropriate source material.

Prior to human contact stream habitat likely exhibited high redundancy. Due to the range of stream habitats found on higher islands (Kaua'i, O'ahu, Maui, island of Hawai'i) compared to lower islands (Ni'ihau, Lāna'i, Kaho'olawe), it is likely that streams on higher islands were able to withstand catastrophic events, like drought, better than streams on lower islands. This is likely due to the higher islands being able to generate orographic rainfall which helped those streams recover more quickly than streams and seeps on lower islands that are more ephemeral and have a higher reliance on climatic events that bring heavy rainstorms.

Historically, the level of stream habitat diversity depended on if the mountains were high enough to generate orographic rainfall and which side of the island the stream was located (windward or leeward). Typically, stream habitats exhibited high representation on higher islands, with more diversity on windward sides of the islands; and low representation on lower islands likely with lower diversity.

Current Condition

Stressors

Fresh water on oceanic islands is important for agricultural, industrial, and individual use. Diversion, channelization, and withdrawals of stream water by humans for these purposes or for flood control is a continual threat to stream habitat quality, even in lowland areas. One-fifth of Hawai'i's streams, mostly on O'ahu, have been channelized, lined, or straightened in order to carry floodwaters away from people and property, stabilize stream banks, or increase the amount of land for development (CWRM, 1993; U.S. Fish and Wildlife Service, 1978a,b). Agricultural chemicals, sedimentation, municipal wastes, invasive species, and changes in turbidity, oxygen content, flow, and water temperature can all lower the quality of the habitat. Feral animals or livestock, and urbanization or land use practices that remove streamside canopy cover, can increase water temperatures and cause eutrophication (Stone, 1989). Furthermore, as climate change causes higher temperatures and longer dry seasons or drought, stream discharge can be reduced significantly, causing irreversible changes.

Channelization and Water Diversion

Streams played an important role in indigenous Hawaiian Culture. Ahupua'a were land divisions which served as political, traditional, economic, and social units of Hawaiian Society based on local watersheds with boundaries running from the mountain summits to the sea. Within each division, native Hawaiians developed agriculture and aquaculture systems that utilized many of the islands' streams to supply the water (CWRM, 1993). Diversion of streamflow for agricultural use was an ancient Hawaiian practice and engineering achievement. Excavations and radio carbon dating suggest these irrigated farming systems started around the 15th century. Typically, these systems dam perennial streams with large rocks, divert the water into ditches, distribute the water to terraced pond fields that were used to grow primarily taro (*Colocasia esculenta*), then divert water back to the stream where it empties into fishponds, estuaries, or the ocean. The sugarcane industry expanded on this ancient Hawaiian practice by diverting streamflow from headwaters and transporting it by ditches and tunnels to distant areas, which were usually dry lowland areas. In 1856, the first ditch diversion for sugarcane irrigation took place on Kaua'i. Since then, complex networks of diversion and transport were used to move water throughout Hawai'i (Lau and Mink, 2006).

About 50% of all streams throughout Hawai'i are diverted for agricultural use of water, and urban streams are highly altered by channelization and straightening for flood control (U.S. Fish and Wildlife Service, 1978a,b; Oki, 2003). About 40 of these are larger stream systems that form stream-mouth estuaries.

Channelizing streams can be detrimental to riparian ecosystems by quickly removing fish and wildlife habitat, destroying streambank vegetation and changing stream depth, velocity and temperature. It can also alter stormwater discharges into wetlands, estuaries, and the ocean. Interrupting stream continuity can also impede migrating native freshwater fish, snails, and shrimp (CWRM, 1993). Stream diversions for development and agriculture can also reduce habitat availability around streams by decreasing flows and water depths (Brasher, 2003).

Channelization and water diversion decrease resiliency of stream habitat. By removing surrounding vegetation, erosion and turbidity increase. Fewer habitat types are available for species, which lowers representation. In the event of drought, water temperature increases which in turn increases plant growth and eutrophication.

Urbanization

Urban development increases the area covered by impervious surfaces. It directly lowers the resiliency of stream habitat by increasing the amount of polluted runoff into the stream. Many urban streams serve as conduits for excess storm drain runoff and over-stressed sewage systems, as well as illegal dumpsites for garbage (CWRM, 1993). All of these are negative impacts to the stream habitat and lower its representation, making it uninhabitable to native species. As urbanization continues to increase, so will stream modification (Brasher, 2003). The removal of canopy will lower the resiliency of the stream habitat, and with the addition of polluted runoff, more streams will become eutrophic.

Recreation

Hiking, swimming, fishing, and/or picnicking along Hawai'i's streams can inadvertently cause harm by trampling vegetation, disturbing terrestrial and aquatic species, and polluting the streams (CWRM, 1993). An increase in human disturbance, for example—trespassing and damage from recreational motorbike riding, can create openings (loss of vegetation and canopy) in the forest near streams. These openings can lower resiliency, which increases stream bank erosion and water temperature, which may eventually cause eutrophication if recreation persists (West Maui Mountains Watershed Partnership, 2018).

Storms, Flash Floods, Erosion, and Sedimentation

A severe flash flood carrying a large debris load of boulders and large tree limbs is capable of pushing adult animals completely out of a stream (as happened with Hurricane 'Iniki in 1992) (Fitzsimons et al., 2008; Parham et al., 2008). Flash flooding events can cause mudslides, stream erosion, push heavy boulders and large vegetation downstream, thus destroying ungulate fencing, bridges, and other manmade channelization/diversion structures. Not only do storms and flash floods cause immediate damage to stream banks (i.e., erosion), but they also wipe out the vegetation that provides canopy cover and bank stabilization, both of which help to prevent erosion.

One such flash flood event occurred on Maui in September 2016, destroying numerous fences in West Maui. 'Iao Valley State Park, located in Wailuku on Maui, closed for months due to severe damage. Damage included an eroded streambed, damage to ungulate-proof fences due to the heavy debris load of boulders and tree limbs, and loss of the stream flow gauge. Other physical structures including the parking lot and associated outbuildings were also destroyed. Another event occurred on Kaua'i in April 2018 when flooding west of Hanalei completely cutoff access to Wainiha and Hā'ena communities for excess of a year.

As mentioned in the Description section, streams in Hawai'i are prone to flash floods because rainfall is intense, drainage basins are small, basins and stream profiles are steep, and channel storage is limited (Oki, 2003). Historically, stream habitats exhibited ideal conditions and could "weather the storm." However, currently, with added stressors such as flooding, streams are much less resilient (reduced riparian area and bank stabilization). Furthermore, redundancy is lowered as development increases, which makes it hard for streams to maintain habitat diversity (low representation) and support native species.

Drought and Wildfire

Severe periods of drought have the potential to negatively impact stream flow for Hawaiian streams by converting perennial streams to intermittent streams, and current intermittent streams and seeps to dry out. With these stream flow conversions, native and nonnative plants will die and dry out from the lack of water, which will also be detrimental to the aquatic flora and fauna. This will cause severe erosion of the streambed and remove canopy cover causing water, if flowing, to be in full sun thus increasing the water temperature and eutrophication. As noted above in the Storms section, an especially severe flash flood can carry a large debris load of boulders and large tree limbs capable of pushing adult animals completely out of a stream (as happened with Hurricane 'Iniki in 1992) (Fitzsimons et al., 2008; Parham et al., 2008). The effect of catastrophic events is exacerbated by other stressors as it changes the quality of the surrounding vegetation making it more susceptible to windfall and erosion. As dry biomass accumulates near streams and surrounding habitats, wildfire has the propensity to occur more frequently and spread faster over greater distances due to the quick burning nature of flashy fuels like dead grass and plant material that can cause the stream temperature to increase.

Drought decreases stream habitat resiliency by decreasing canopy cover, which increases water temperature. During long periods of drought, high temperatures can cause the soil to dry out and erode, and also cause eutrophication. Drought also decreases redundancy. Without orographic rainfall, streams cannot support communities of native species. This would also result in a decrease in representation because without rainfall, stream diversity decreases.

Invasive Species

Early immigrants and settlers brought domestic animals and plants to Hawai'i. Over time, some of these pigs (*Sus scrofa*), deer (*Axis axis*), goats (*Capra hircus*), sheep (*Ovis orientalis*), and cattle (*Bos taurus*) ran wild, trampling and eating native plants, spreading seeds and spores from nonnative vegetation, increasing erosion and siltation due to trampling through streambeds, causing streambank alterations, and leaving feces on stream banks that lead to elevated bacterial and nutrient levels (CWRM, 1993). The long list of invasive species includes terrestrial and aquatic plants and animals. Some introduced species have not proliferated, and a few appear to be harmless. However, many of these species have become invasive and have exerted negative effects on the islands' flora and fauna, especially at stream habitats. Entire streams and estuaries have become choked with nonnative vegetation to the point that native plants are crowded out, egg-laying sites for stream fishes and invertebrates are buried beneath vegetation, mud, and silt, and the water no longer has sufficient dissolved oxygen to support most aquatic animals. Nonnative and invasive vegetation decrease stream bank stabilization due to shallow root systems, which leads to erosion, and adds sediment to the stream that eventually is discharged into the ocean. Nonnative freshwater fish species currently outnumber native stream species, and the number of introduced species is likely to increase in spite of efforts to protect native species.

Invasive species lower resiliency by dominating riparian areas. Invasive plant species have shallow root systems that are ineffective at stabilizing streambanks. This results in erosion and turbidity, following normal rainfall. Invasive species also lower representation by dominating stream habitats. They outcompete native vegetation, which results in low habitat diversity. Native plant and animal species cannot compete in a stream habitat dominated by invasive species (Figs. 5–13).

Conservation Efforts

Protection of streamside vegetation to preserve natural aquatic temperature and light conditions and sources of food for stream organisms is important. Feral ungulates such as pigs, deer, goats, sheep, and cattle should be removed from watersheds drained

Fig. 5 Summary of stream length through four different habitat quality types. From: Reeves, M. K. and Amidon, F. (2018). *Habitat status assessment methods – Hawaii, current condition summaries*, pp. 439. Fig. 9 The proportion of stream types by total length on Hawai'i. From: Reeves and Amidon, 2018.

by nearly pristine streams, and prevention of pollution from development and agriculture in these areas should be emphasized. Watershed partnerships, government agencies, and nonprofit groups protect streams and entire watersheds by fencing areas to keep ungulates out, removing ungulates within the fenced areas if required, removing invasive plant species to promote native plant growth, and organizing education and outreach events focused on the importance of protecting Hawaiian streams and watersheds. Channelization projects that result in replacement of natural substrate with artificial bottom material, reduction of stream channel length, and vegetation removal should be avoided where feasible. Active conservation education about the value of Hawaiian streams is necessary along with educational materials available from environmental groups that help inform the public about conservation issues (Stone, 1989). Watershed groups, government agencies, and nonprofit groups are playing a critical role in restoring stream functions through watershed plans and restoration activities. As a result, their efforts generally increase resiliency, redundancy and representation.

Management

Management actions to address stressors can help to improve stream habitat conditions. Implementing feral ungulate control and invasive plant control will promote growth of native vegetation along riparian areas, which will decrease erosion and increase resiliency of stream habitats during flood events. Restoring and enhancing populations of native pollinators and plants can increase canopy cover over streams, which will keep them cooler and increase redundancy of stream habitats during drought events. Educating the community and implementing monitoring programs can keep communities aware and get them involved in actively working to conserve stream habitats. Over time, this will increase representation of stream habitats in their ability to adapt to changing environmental conditions.

Nonnative animal control

Feral ungulates have a serious effect on native ecosystems—particularly on the ground layer of vegetation. Native plants evolved without the need to defend themselves against large animals; most have no thorns or toxins to keep animals from grazing on them. Very few native plants have deep root systems, and cannot survive when the soil around them has been trampled and compacted. Impacts to the streambanks due to trampling from ungulates can cause erosion and stream incision. Small mammals, such

Fig. 10 Percent of total island stream length based on land ownership. From: Reeves and Amidon, 2018.

as mongoose (*Herpestes javanicus*), rats (*Rattus rattus*), and mice (*Mus musculus*), can also be a serious threat. They prey on native birds and nests, feed on the seeds and seedlings of native plants, and carry diseases such as leptospirosis which can harm humans as well as animals when it gets into stream systems. Actively removing animals is often required to limit their effects. Public hunting and staff control, fencing, one-way gates, and other innovative actions are components of successful animal control efforts attempted throughout Hawai'i.

Nonnative plant control

Nonnative and invasive plants can pose serious threats to the native Hawaiian ecosystems including streams. Certain weeds have the ability to spread quickly, establish themselves in many types of forest habitats, and take over large areas. They do this by out-competing the native plants, particularly at the seedling stage. Control of these weeds requires a variety of measures, including mechanical removal (machines or hand), applying herbicides, or biological control methods.

Restoration and habitat enhancement

Management of native ecosystems may also require restoring or enhancing existing populations of native pollinators (birds and insects) or plants. Increasing the number of existing individuals of rare plants through propagation and out-planting programs or increasing the number of rare birds through captive breeding and release are among the tools available. Maintaining or restoring the dynamic natural processes is the goal of native ecosystem protection and restoration programs. Outplanting native species near streams can aid in lessening streambank erosion and provide canopy cover keeping the streams cooler.

Monitoring

A comprehensive monitoring program that helps managers understand what resources are present in each specific area, their health and abundance, and what threats are present can help to inform management for different streams and along different stream reaches. Monitoring actions include periodic surveys to gather information on the status and condition of resources, the status and extent of threats to those resources, and the success or failure of management actions.

Fig. 11 Total length of streams based on land ownership. From: Reeves and Amidon, 2018.

Education and outreach

Without a clear understanding of what native ecosystem management involves and why it is needed, public support for these programs will be difficult to obtain. Information and education are incorporated into protection efforts whenever possible. To obtain public support for management, an education program that includes products such as informational brochures, video productions, speakers to address schools and community groups, and active outreach and volunteer programs are all important conservation strategies utilized by Hawaiian conservation groups and agencies.

Land Protections

The State of Hawai'i has statewide the Natural Area Reserves System (NARS) that was established to preserve in perpetuity specific Hawaiian land and water areas that support assemblages, as relatively unmodified as possible, of the natural flora and fauna, or notable geological sites. The system presently consists of 21 reserves on five islands, encompassing 123,810 acres of the State's most unique ecosystems. The diverse areas found in the NARS range from marine and coastal environments to lava flows, tropical rainforests, and even an alpine desert.

Many of these NARS encompass numerous streams and the surrounding habitat. One of the statutory responsibilities of the NARS Commission is to conduct studies of areas for possible inclusion and recommend to the governor and the department areas suitable for inclusion within the reserves system (HRS § 195-7). Other reserves that protect and actively manage Hawai'i's native ecosystems including streams (Figs. 9 and 10) are the National Park Service, The Nature Conservancy of Hawai'i, USFWS National Wildlife Refuges, State of Hawai'i Wilderness Parks, and National Historic Parks.

Laws and Regulations

The United States Army Corps of Engineers' (USACE) regulatory efforts authorized by the Clean Water Act and the Rivers and Harbors Act protect a wide variety of aquatic resources, including wetlands, rivers, streams, tidal waters, coral reefs, shellfish

Fig. 12 Length of streams through different reserve types. From: Reeves and Amidon, 2018.

beds, and the oceans. The permit process is designed to minimize environmental impacts of construction and dredging activities in U.S. waters and to ensure such efforts are thoughtful and coordinated. The Corps Regulatory Program provides oversight of discharges of dredged or fill material into waters of the United States, and construction or other work in navigable waters of the United States, under Section 404 of the Clean Water Act and Section 10 of the Rivers and Harbors Act of 1899. A proposed project's impacts to these areas will determine what permit type is required. The USACE Regulatory Program is committed to protecting the Nation's aquatic resources and navigation capacity, while allowing reasonable development through fair and balanced decisions. The USACE evaluates permit applications for essentially all construction activities that occur in the Nation's waters, including streams and wetlands. The Honolulu District evaluates about 300 permit applications each year under its regulatory program. The Corps authorizes permits under Section 10 and 404 permits throughout Hawai'i.

The Hawaii State Water Code (HRS 174C) provides a Commission on Water Resources Management (CWRM) with authority to establish minimum instream flow standards to protect stream habitats for fish and wildlife. Specifically, the Code mandates that public trust uses such as minimum instream flows for ecological integrity and traditional cultural practices must be fully addressed before off-stream allocations can be granted. In 1988, legislators also asked the State Commission on Water Resources to set up a Wild and Scenic Rivers System, although only limited progress has been made in this regard. Streams proposed for such designation include Kahana Stream on O'ahu; Kahakuloa and Hanawi on Maui; Waimanu on Hawai'i; Kilauea, Hanalei, and Lumaha'i on Kaua'i; and Wailau and Pelekunu on Moloka'i (Stone, 1989).

The CWRM has recently implemented Interim Instream Flow Standards (IIFS) for numerous streams on Maui, and is in the process of additional designations on that island. For over 100 years, the majority of the perennial streams on Maui had been diverted to the island's central isthmus for sugarcane irrigation. On April 24, 2014, the CWRM settled a contested case involving West Maui streams by restoring flows in four major windward catchments (Waikapu, Wailuku, Wai'ehu and Waihe'e). Even after the closure of the last Maui sugarcane plantation in 2016, however, water from streams on the windward coast of East Maui continued to be diverted from this sector for other uses (KHON2, 2018), over the objections of various stakeholder groups. On June 20, 2018, the CWRM issued the largest water rights decision in state history. The decision involved 27 streams on East Maui, restoring flows to many of these diverted systems and requiring all future diversions to be fully justified. The direction of these recent legal decisions means many streams on Maui and elsewhere in Hawai'i may now have the opportunity to gradually return to

Fig. 13 The proportion of total island stream length in reserves. From: Reeves and Amidon, 2018.

more natural flow regimes similar to those that prevailed when the first Polynesians arrived in the islands, which will benefit native aquatic biodiversity.

Habitat Viability

Stream habitat currently exhibits relatively low resiliency compared to historical stream habitats. Many stream habitats no longer have native canopy to keep the water cool in the event of a drought. Similarly, many stream habitats don't have a canopy to keep the soil moist for riparian and buffer zone vegetation that prevents erosion during drought. In the event of a fire, if riparian vegetation is affected, the stream will likely be susceptible to erosion, eutrophication, and also to reestablishment by invasive species, since native riparian vegetation is often poorly represented.

Currently, stream habitat redundancy is still greater on higher islands compared to lower islands. However, redundancy overall is reduced across the Hawaiian islands due to stressors such as channelization, water withdrawals, development, invasive species, etc. For example, most O'ahu streams, despite being in or near highly developed areas, will likely recover from drought more quickly than seeps on Lāna'i, which were severely impacted by agriculture and feral ungulates. Both types of stream habitats, however, will now recover at a slower rate overall compared to how they would have recovered historically. These added stressors lower redundancy across the board by decreasing the overall number of flowing stream systems across the islands, but higher islands will still recover faster because of their ability to capture orographic rainfall.

Stream habitat on higher islands currently still have higher representation than stream habitat on lower islands because of their ability to generate orographic rainfall. However, compared to historical stream habitat, representation is lower across all islands. Urbanization and invasive species are a couple of the main stressors that lower representation and diversity of stream habitat to the point to where no native species can compete.

Future Scenarios

The condition of stream habitat in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

- (1) *Conservation values*: Stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) *Laws and biosecurity*: National, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented. (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) *Development or conservation planning*: National, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios.

The four foreseeable future scenarios considered in this habitat assessment are:

Future Scenario One, Status Quo—The most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—A slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—A moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of stream habitat in Scenario One, the status quo, was characterized from an assessment of change over time in stream land cover obtained from existing land cover maps (Amidon and Reeves, 2018a,b). Based on these land cover maps, an annual rate of change for Stream habitat was estimated, and a projected change (in acres/hectares) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the Stream habitat that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged.

The future conditions of stream habitat for Scenarios Two, Three, and Four cannot be quantitatively (acres/hectares) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of Stream habitat under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018a,b). Impacts from other sources of human activities or human-caused habitat stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation.

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions, which occurs on the order of centuries rather than years. Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related habitat stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future habitat viability.

Future Scenario One, Status Quo

Summary: Scenario One is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in the habitat as described below.

Description: Using the current rate of change, the land cover for stream habitat was calculated for the year 2035. The projected change in land cover by 2035 is the only future scenario with quantitative values (acres or hectares). The anticipated changes, under Scenario One, for each of the habitat stressors affecting stream habitat are given in Table 1.

An expanding human population and increased development and general land use on all inhabited islands is anticipated, and therefore habitat stressors are expected to increase at a small annual rate. Exceptions are a small to moderate annual rate of increase for development, wild fires, and surface air temperature, and a small annual rate of decrease for precipitation. Development of land for residential, commercial, and agricultural purposes will continue.

Because the Scenario One biosecurity CMP remains unchanged while the population and development continue to grow, an increased potential for new invasive species and new diseases (particularly those affecting native plants) exists. The introduction of additional plant diseases and invasive species may enhance the conditions that support wildfires.

Under this scenario, rivers, streams, and seeps will likely show a decrease in condition and abundance compared to current conditions. This decrease in representation is attributed to increase in human population and development that will decrease water availability of rivers and streams since more water will be diverted for human and agricultural uses. Redundancy will likely decrease, compared to the current condition, especially on lower islands because of their inability to generate orographic rainfall. Current streams that are year-round will increasingly become intermittent. Streams that are currently intermittent may become eliminated, especially those on leeward sides of the Hawaiian islands. Seeps on high elevation islands may increasingly become intermittent, while seeps on lower elevation islands may increasingly become eliminated. Without updating laws to accommodate increases in recreation human presence/abundance-related stressors, there is the potential for rivers and streams to be utilized more frequently, which will slightly increase the spread of invasive species, transforming native streambanks to nonnative vegetation. Root systems and resource requirements of these invasive plant species may likely increase erosion and sedimentation of stream habitats. Increase in these stressors will likely lower resiliency of stream habitats, compared to the current condition. For example, a slight decrease in bank stability is likely to occur due to invasive ungulates and humans trampling the edges of the rivers and streams. So in the event of a storm, flooding will likely have an increased negative effect on riparian and stream bank areas because of a decrease in riparian quality and bank stability caused by ungulates and human recreation. Erosion and sedimentation will increase, and riparian vegetation may be decreased. Decrease in riparian vegetation will likely decrease canopy cover, which may increasingly lead to eutrophication.

Overall, based on this analysis, it is anticipated that under this scenario, rivers streams and seeps will decrease, relative to current condition, in condition and abundance, and will have a lower likelihood of supporting native ecological communities that depend on rivers and streams. By 2035, it is anticipated that rivers, streams and seeps will likely have lower redundancy and representation across the Hawaiian islands, and be less resilient to stochastic events.

Table 1 Responses of Stream habitat stressors in foreseeable future scenarios.

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans

Future Scenario Two

There is a slight increase in the CMPs that marginally improves conservation management.

Summary: Conservation Agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas.

Description: Scenario Two is essentially “status quo” with minor improvements in the three CMPs. The anticipated changes, under Scenario Two, for each of important habitat stressors for (habitat name) habitat are given in [Table 1](#).

Though there is an expanding human population in Scenario Two, development is not expected to substantially increase. A slightly improved biosecurity effort should help reduce invasive species and plant diseases but increases are still expected. The small increased support of natural resource management in the CMPs is not expected to greatly alter wildfire frequency and intensity, but these might (lower slightly) compared to Scenario One. The CMP supported conservation will not prevent, mitigate, or reverse the impacts of climate change-related stressors.

Under this scenario, rivers and streams are predicted to slightly increase, relative to status quo, in condition and abundance. Although seeps will also experience a slight improvement in conservation actions, it will not be enough to significantly change the declining trend described in Scenario 1. Instead, we anticipate that the rate of decline of seeps will likely begin to plateau, relative to status quo, in condition and abundance. The slight increase in representation of rivers and streams is based on assumptions that there are slightly better conservation values and laws protecting stream habitats from further degradation. In areas with population increase, there may be stricter policies that require an increase in stream habitat restoration. However, these efforts will likely have little to no effect on seeps, as their representation plateaus at status quo, because there will be no change in hydrology, despite the needs of an increasing population. Conservation values and laws should slightly increase in stream habitats where human recreation increases in order to mitigate erosion, sedimentation, bank alteration, water pollution, and the spread of invasive species. Conservation values and laws should also slightly increase to mitigate the increase in climate related stressors like temperature and flooding. Removing invasive species and outplanting native species will be key in maintaining bank stability and canopy cover, which will minimize sedimentation and eutrophication. Redundancy of rivers, streams and seeps will likely plateau at the status quo across the Hawaiian islands, with higher islands being able to recover faster because of their ability to capture orographic rainfall. Although some stressors are projected to slightly increase, laws and values are also projected to slightly increase in order to balance out and mitigate negative effects of those stressors. Resiliency of rivers and streams will likely increase slightly as a result of slight increase in conservation values and laws. Those conservation values and laws will likely have no effect on seeps; therefore, resilience of seeps will likely plateau at the status quo. Stricter policy will need to occur in order to allow an increase in groundwater recharge before we see an increase in seep resiliency.

Overall, based on this analysis, it is anticipated that under this scenario, rivers and streams will slightly increase, relative to status quo, in condition and abundance, and will have a slightly higher likelihood of supporting native ecological communities that depend on rivers and streams. The rate of decline of seeps is anticipated to plateau (stay similar to the condition described in the Current section, above), likely and will therefore have a slightly increased likelihood of being able to support native ecological communities that depend on seeps, relative to the condition of the habitat described in Scenario 1. By 2035, it is anticipated that rivers and streams will likely have slightly higher representation and resiliency across the Hawaiian islands. Redundancy of rivers and streams will likely plateau across the Hawaiian islands. Representation, redundancy and resiliency of seeps will likely plateau at current levels.

Future Scenario Three

There is a small to moderate decrease in conservation actions in the CMPs that substantially decreases conservation management.

Summary: All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible.

Description: Scenario Three has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for economic development over the conservation of native habitats. Areas that cannot support development become the only areas of free-living native species. The anticipated changes, under Scenario Three, for each of habitat stressors important to (habitat name) habitat are given in [Table 1](#).

An expanding human population requires increased land use for agriculture and development. Biosecurity controls are significantly weakened in this Scenario leading to an increase in invasive species problems and new plant diseases. Combined together, these factors will result in substantial increases of wildfire frequency and extent. The substantial loss of CMP supported conservation may locally aggravate the impacts of climate change-related stressors.

Under this scenario, rivers and streams are predicted to severely decrease, relative to status quo, in condition and abundance. Seeps on higher elevation islands are predicted to severely decrease in condition and abundance, some becoming ephemeral; while seeps on lower elevation islands are expected to become ephemeral or eliminated. This decrease in representation is based on assumptions that development in watersheds will increase so much that rivers and streams will become channelized, seeps will be lost, and hydrology will be altered so severely that it will drastically lower water availability of streams. Increase in temperatures and longer periods of drought will eliminate water resources, and as a result likely dry out these stream habitats. Long periods of

drought will also dry out riparian areas and make them susceptible to fire. Increased fire events will eliminate riparian vegetation and prevent regrowth, decreasing bank stabilization. A high increase in flood events will likely wipe out riparian areas further increasing erosion and sedimentation. Resiliency will be drastically reduced with no canopy to keep the water and soil cool, leaving the stream susceptible to sedimentation and eutrophication. Redundancy will be drastically lowered across the Hawaiian islands; however, higher islands will likely retain some level of resiliency and water flow for a longer time period because of their ability to capture orographic rainfall. Lower islands that only have seeps may likely only see seeps after storm events, if at all. In this scenario, conservation values and associated laws are minimal, so there will likely be little to no funding allocated to watershed or stream restoration and maintenance.

Overall, based on this analysis, it is anticipated that under this scenario, stream habitats will severely decrease, relative to status quo, in condition and abundance, and will have a much lower likelihood of supporting native ecological communities that depend on stream habitats. By 2035, it is anticipated that stream habitats will likely have lower representation and redundancy across the Hawaiian islands, and be less resilient to stochastic events.

Future Scenario Four

There is a moderate to large increase in conservation actions in the CMPs that substantially improves conservation management.

Summary: An overt and robust, active, ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of native habitats and ecosystems, and to actively restore and expand these habitats and ecosystems.

Description: A substantial emphasis on natural resource conservation is present in the three CMPs, reflecting increased societal concern for declines in natural habitats and biodiversity. Active and well-supported natural resource management begins to restore these habitats and ecosystems and expand their landscape areas. The anticipated changes, under Scenario Four, for each of habitat stressors important for (habitat name) habitat are given in [Table 1](#).

The needs of an expanding human population are addressed through more efficient land use governance based on redevelopment rather than development of undeveloped areas. Modern and novel agricultural practices focus on those that do not affect existing natural areas or areas needed for native habitat restoration. Substantially improved biosecurity regulations decrease introductions of invasive species and plant diseases. These improved land management actions result in decreased wildfire frequency and extent. The substantial increase in CMP supported conservation may locally mitigate the effects of climate change-related stressors, but climate change is expected to continue.

Under this scenario, rivers, streams and seeps are predicted to increase, relative to status quo, in condition and abundance. This increase in representation is based on assumptions that all human presence/abundance-related stressors will decrease. Decrease in these stressors (i.e., stricter regulations limiting water diversions and withdrawals) will likely increase water availability of stream habitats across the Hawaiian islands. Decrease in these stressors along with an increase in conservation values and associated laws will likely improve riparian areas, further increasing bank stabilization and decreasing erosion. Funding will likely be allocated to stream restoration and maintenance along entire watersheds, increasing the value of the ecosystem services stream habitats provide. As the ecosystem services provided by stream habitats are so highly valued by the public, it is anticipated volunteer efforts and community involvement will increase to restore stream and riparian habitats to historically high levels. Resiliency will likely increase since restored riparian areas will provide canopy cover to keep the water and soil cool, preventing eutrophication and erosion of stream banks during periods of drought. Redundancy will also increase across the Hawaiian islands at all elevations. It is likely stream habitats on the higher islands will recover/rebound more quickly because of their ability to capture orographic rainfall. Lower islands with ephemeral seeps will likely now have seeps that occur year-round. Lower islands with seeps that occur year-round will likely now see these seeps turning into ephemeral streams, especially following storm events. Ground water recharge will likely increase, which will increase overall water availability, even on lower islands that don't capture orographic rainfall. Seeps on higher islands will also increase in condition and abundance, relative to status quo, because of overall increase in ground water recharge.

Overall, based on this analysis, it is anticipated that under this scenario, stream habitats will increase, relative to status quo, in condition and abundance, and will have a higher likelihood of supporting native ecological communities that depend on stream habitats. By 2035, it is anticipated that stream habitats will likely have higher representation and redundancy across the Hawaiian islands, and be more resilient to stochastic events.

Abstract

This article provides a review of the flowing water, or lotic, ecosystems found in the Mariana Islands, with a particular emphasis on perennial streams. The geology, hydrology, and biota of these streams is discussed for the islands of Guam, Rota and Saipan, the only islands in the archipelago which possess perennial stream ecosystems. Current integrity and future conservation of these ecosystems is also evaluated in the context of human-mediated stressors such as wildland fire, aquatic invasive species and climate change. A provisional assessment is provided as to how the condition of such streams may change over time based on future climate scenarios.

Introduction

The current article provides a review of the flowing water, or lotic, ecosystems found in the United States Territory of Guam and the Commonwealth of the Northern Mariana Islands (collectively referred to hereafter as the “Mariana Islands” or “Marianas”), with a particular emphasis on perennial streams. The Mariana Islands consist of an island arc in the northwest Pacific to the east of the Philippines, containing 15 islands of volcanic origin, all lying in tropical latitudes (for a general contextual overview of geography and ecology of the Mariana Islands as a whole see other chapters in this work). The geology, hydrology, and biota of these streams is discussed, and their current condition evaluated in the context of human-mediated stressors, including wildland fire, aquatic invasive species and climate change.

Of the approximately 102 perennial streams currently recognized within the Mariana Islands, including tributaries to larger systems, nearly all occur on Guam (Taboroši et al., 2005), with the exception of one perennial stream system each on the islands of Rota and Saipan. No perennial streams occur on any of the other 12 islands in the archipelago. Consequently, the larger portion of the following discussion regarding stream ecosystems within the Mariana Islands concerns the island of Guam, with secondary emphasis on Rota and Saipan.

Overall, streams in the Mariana Islands are similar to those elsewhere in the tropical insular Pacific in exhibiting the following characteristics:

1. They are prone to exhibit rapid, flash flood-like discharge patterns (Fig. 1) due to their relatively small catchment sizes, steep channel profiles, and limited capacity for stream channel storage (defined as the overall capacity for water within the boundary of a given stream’s banks). The rainfall events feeding into these catchments are also often intense and episodic, frequently as a result of tropical cyclones in the latter half of any given calendar year, leading to rapid increases in stream discharge volume over short periods of time.
2. They are short in length compared to streams on the continents or larger land masses. For example, streams on Guam range from 1 to 7 miles (1.6 to 11.3 km) in length, with shorter and more linear catchments on the south and west flanks of the island, and longer, more integrated catchments draining eastward from the island’s center (Figs. 5 and 6). Stream systems on Rota and Saipan are even shorter, with the only perennial stream on Saipan being <1.5 miles (2.4 km) long, and the only perennial stream on Rota being a mere 0.87 mile (1.4 km) in length (Camacho et al., 1997).
3. They possess stair-step bed profiles containing one or more waterfalls, defined as a cascading feature with a gradient of 40% or greater, somewhere along their length (Figs. 6 and 7). Such breaks in the bed profile occur due to steep island topography, coupled with an underlying petrology consisting of successive layers of limestone, lava and lateritic or saprolitic soils that exhibit varying degrees of resistance to erosion. Such waterfalls can also represent barriers to the upstream migration of certain aquatic organisms.

Fig. 1 An annual hydrograph for the Pago River on Guam for the year 2017, illustrating the flashy nature of discharge in this catchment, and the significant clustering of periodic flood peaks during the typical typhoon season of the year from July to December, both patterns being typical of Marianas Streams. The system reverts to base flow only at certain points in the dry season from January to June. Data from US Geological Survey.

4. Due to the locations of these streams on oceanic islands that have never possessed connections to larger continental areas, their biotas are limited and disharmonic, lacking many groups of fishes and aquatic insects typically encountered in continental settings. For example, there are no primary freshwater fishes, defined as those that complete their entire life cycle in fresh water. In addition, there is an absence or very low species richness of certain aquatic insect groups such as mayflies, caddisflies, and stoneflies that are important components of stream food webs on the continents. Instead, the biota of Marianas streams consists of a limited suite of fishes, shrimps, mollusks and insects specifically adapted to exploit the particular habitats offered by these systems, often through amphidromous life cycles, meaning that they possess a marine planktonic larval stage, with the post-larvae migrating back into freshwaters, where the adult stages live and reproduce.

These characteristics render streams in the Mariana Islands, and the Pacific islands in general, hydrologically and biologically distinctive in comparison to those elsewhere in the world.

Stream Ecosystem Classification

An ecosystem classification scheme for the inland waters of the insular Pacific, including both streams and wetlands, was proposed by Polhemus et al. (1992). Under this system, three classes of streams were recognized: (1) Intermittent Streams, consisting of channels that lack permanent surface flow, but may contain flowing water after heavy rains, and sometimes retain permanent pools at exposed bedrock sills or in other areas of low substrate permeability; (2) Interrupted Streams, which support perennial flow in their upper reaches, but become dry as this flow sinks into the bed further downstream, so that there is no continuous flow all the way to the sea except during the wet season or after major rainstorms; and (3) Perennial Streams, which maintain flow throughout their entire length and discharge continuously to the ocean during all seasons, irrespective of seasonal variations in precipitation. All of these stream types occur in the Mariana Islands, but the current article concentrates primarily on perennial streams, which support the richest and most persistent biota. Due to a lack of established definitions in the scientific literature, we make no attempt to draw a formal distinction between "rivers" and "streams", although both terms are used for features in the Marianas, with the Talofofo River on Guam being the largest and longest stream in the archipelago.

It should also be noted that man-made diversions may convert perennial streams into interrupted streams by dewatering certain reaches, although in this case they are considered as a separate, Artificially Interrupted Streams ecosystem class. The waters diverted from such streams are in turn often fed into another flowing water ecosystem class, Artificial Ditches and Flumes, consisting of man-made channels which carry flow laterally across natural drainage divides. Such anthropogenic systems tend to have limited biota, often consisting of introduced species. Although widespread in the Hawaiian Islands, such artificial aquatic ecosystems are of relatively limited extent in the Mariana Islands. Examples on southern Guam include the diversions from the Almagosa and Bona springs, which are conveyed to the Fena Valley Reservoir storage system (Ward et al., 1965).

Along the length of any given perennial stream, Polhemus et al. (1992) also recognized three discrete divisions: (1) the Headwater Reach, lying above 800 m elevation or having a gradient of >30%, or both, and often exhibiting a significant amount of bedrock exposure in the channel (Fig. 3); (2) the midreach, lying between 800 m and 50 m elevation, with a more moderate gradient, and a bed substrate consisting of mixed rocks, cobble and gravel, with limited representation of bedrock or fine sediment; and (3) the Terminal Reach, generally lying below 50 m elevation, with a low gradient, and a bed substrate containing large amounts of gravel and fine sediment. The boundary between the midreach and the terminal reach is often marked by the first significant barrier in the stream bed, such as a waterfall, that bars the upstream migration of itinerant marine fishes (Fig. 7).

Stream terminal reaches in many cases transition into estuaries, where limnetic stream waters (those with 0 ppt of salinity) intergrade with euhaline marine waters (32–36 ppt salinity) through an intermediate mixohaline estuary zone (1–31 ppt salinity). Such estuaries are tidally influenced, and provide corridors for the entry of certain transient marine biota into stream terminal reaches, as well as the transit of larval and juvenile amphidromous species which spend portions of their life cycles in both freshwater and marine environments. The upper extent of such estuaries is generally defined by the presence of some degree of salinity, coupled with the upper limit of measurable tidal fluctuation. In many cases such estuaries are often vertically stratified in terms of water chemistry, with a fresher, nearly limnetic layer at the surface, and a denser, more saline layer on the bottom. Such stratified layers may also exhibit dichotomous current regimes, with low salinity waters flowing out at or near the surface, while higher salinity waters flow in at or near the bottom.

A final flowing water ecosystem class in the Marianas consists of Rheocrenes, which are flowing springs, often emerging from and passing over bedrock faces. Small rheocrenes are present on most of the islands in the Marianas, irrespective of island size, although they often have small discharge volumes and flow for only short distances. Although generally insufficient to support fishes or crustaceans, they may provide habitat for native aquatic insects.

Hydrology

The ultimate source of water for all perennial streams in the Mariana Islands is seasonal and orographic rainfall. Such precipitation inputs can be substantial in the Mariana Islands, with the average rainfall on the entire island of Guam, averaged across the wet and dry seasons of the year, amounting to approximately one billion gallons per day (Ward et al., 1965). Some of this is recycled to the atmosphere as evapotranspiration, with 4 inches (10 cm) of rainfall per month being necessary to meet such demands in the river basins of southern Guam. Below this amount, the vegetation becomes drought-stressed, while above this amount excess runoff and spring discharge will increase stream flow (Ward et al., 1965). In certain areas with favorable geology, such as southern Guam and a few small areas on both Rota and Saipan, a certain proportion of the precipitation may also be captured subsurface as perched groundwater lying up to several hundred feet above sea level, where it is trapped between a porous overlying limestone caprock formation and less permeable underlying basalts (Gingerich, 2003). Such perched groundwater emerges at the contact between the limestone and the basalt, forming permanent seeps and springs that produce continuous base flows in stream headwaters. The remaining rainfall that is not lost to evapotranspiration or captured as groundwater runs off directly into the sea. Because the proportion of rainfall that runs off is high on these islands, especially in those areas of impermeable volcanic terrain where most stream channels form, the discharge rates of even their perennial streams are subject to notable variations between the wet and dry seasons, and dry spells of only a few weeks can lead to significantly diminished stream flows (Ward et al., 1965).

Outside of Guam, Rota and Saipan, the remaining 12 islands within the Mariana Archipelago lack flowing streams altogether, due to their small sizes coupled with porous limestone or recently erupted volcanic substrates that allow rapid percolation of rainfall into aquifers. These groundwaters discharge as basal springs along the coasts, thus precluding the formation of perennial streams at higher elevations. Despite a dearth of perennial streams within the Mariana Archipelago as a whole, nearly all of the islands do possess perennial seeps, which can be important habitat for certain aquatic insect species. During the wetter months of the year the various intermittent streams on Rota and Saipan will also exhibit some degree of surface flow, although the biota of such transient aquatic ecosystems is often limited to dispersive and opportunistic aquatic insect species such as dragonflies.

In perennially flowing Marianas streams, there is limited accumulation of sediment, leaf litter, and other loose debris, due to continuous flow coupled with periodic strong flushing by flash floods, which are triggered by convectional rains in the mountains or strong weather events such as tropical cyclones (Fig. 1). While storms in the Mariana Islands can occur any time of the year, the typical typhoon season runs from late June through December, with the peak occurring between late August and mid-November (Lander, 1994). During this period, mountain streams may experience repetitive high discharge peaks over a short period, and remain in a near-constant state of recovery from the most recent flood. Although potentially destructive, flash floods may also produce positive effects by flushing away debris that might otherwise contribute to oxygen depletion during periods of low water; removing sediments that can smother the eggs of stream animals; and opening up stream mouths where they flow into the sea, thereby allowing for biotic interchange through estuaries.

Except in the few areas of remaining intact native forest, such as those tributaries above the Fena Valley Reservoir in the upper Talafofo River basin of Guam, canopy cover above Marianas streams is often 25% or less, depending upon the immediately surrounding habitat. Perennial streams on Guam flow for most of their lengths through a variety of anthropogenically transformed landscapes (Fig. 2), including altered native or non-native forests of variable density, often dominated by coconut or betel nut palms; low stature *tangan-tangan* (*Leucaena leucocephala*) woodland; ironwood (*Casuarina equisetifolia*) savanna; fire-mediated grasslands dominated by swordgrass (*Miscanthus floridulus*); fern banks; marshy areas with reeds (*Phragmites karka*); and even urban channelization (Muller-Dombois and Fosberg, 1998). As such, it is difficult to make generalizations regarding a “typical” riparian zone for streams in the Marianas (Boyer et al., 2009), except to note that shading on Guam is often low due to destruction of surrounding vegetation by wildland fire (Fig. 3), whereas those few stream reaches on Saipan that harbor permanent water are heavily shaded (McCagan et al., 2008).

The amount of canopy cover is important as it relates to water temperature and the formation or absence of algal growth. Cool water has a greater capacity to hold oxygen, an important factor for supporting stream fauna. Conversely, streams without canopy cover are more exposed to the warming effects of the sun, which can affect plant and animal species composition and abundance.

Fig. 2 Riparian ecosystems of Guam.

Fig. 3 The headwater reach of the Ylig River on southern Guam, illustrating significant bedrock exposures in the channel, and relatively low shading due to the absence of an overtopping riparian canopy. Photo: Dan A. Polhemus.

Streams over-exposed to sunlight may develop thick mats of algae attached to the rocks, floating algal mats, surface scum, and a microbial sheen. These are all indicators of eutrophication, an excessive richness of nutrients due to runoff which causes a dense growth of aquatic plant life (NRCS, 2001) but is deleterious to other organisms.

Island of Guam

The island of Guam lies at 13°27'N, 144°47'E, and is the most populous of the Mariana Islands, with 162,000 residents. The island is of hybrid geological origin, consisting of volcanic uplands on the southern half and an elevated, cliff-bound limestone plateau in the north (Figs. 4 and 5), with these two geologic units being separated by the Pago-Adelup fault, which cuts transversely across the

Fig. 4 The surface geology of Guam, as simplified from the geological map of Siegrist and Reagan (2007).

Fig. 5 The topography of Guam, illustrating the relatively flat-lying limestone plateau in the north of the island which is devoid of streams, and the more heavily dissected volcanic terrain in the southern half of the island, which contains the majority of the perennial streams in the Marianas.

island (Taboroši et al., 2005). Despite consisting of only a single island, the Territory of Guam has a total land area of 212 miles² (549 km²), which is larger than the combined land area of all the islands within the remainder of the Mariana Island chain. The highest point on the island is Mt. Lamlam, in the southern highlands, which reaches 1334 ft. (407 m.). The coastlines of Guam are for the most part steeply dropping, although there are extensive beach areas on the western side at Tumon and Agana bays, and a reef-fringed lagoon in the south at Merizo. Native forest cover on Guam was extensively damaged during World War II, but has regenerated in many areas of the north, which are under military control, while continuing to suffer regular damage from poorly controlled wildland fires in the south. In contrast to the remainder of the Mariana Islands, Guam harbors a large number of perennial streams (Taboroši, 2013), all of which occur in the volcanic southern portion of the island (Fig. 5). These include 46 stream catchments of greatly varying sizes (Best and Davidson, 1981), which can be grouped into 19 major watershed units (Fig. 6).

Fig. 6 The major watershed units of Guam, also showing the locations of major waterfalls, which represent barriers to the upstream migration of many euryhaline fish species.

Guam exhibits a pattern of alternating annual wet and dry seasons similar to the rest of the Marianas, with a wet season from July to December, during which two-thirds of the annual rainfall occurs in a typical year (Lander, 1994), and a drier season from January to June, during which mean monthly rainfall is < 8 inches (Johnson, 2012). It is estimated that somewhere between 12 and 30% of Guam's wet season rainfall is produced by the passage of tropical cyclones within 180 nautical miles, with the remainder arising through convection (Lander, 1994; Johnson, 2012). Although rainfall data has been collected from over 60 sites on the island since 1906, most of these gauges have short periods of record, so understanding of long-term rainfall climatology from 1950 to the present is largely based on records from a limited number of gauges at Umatac, Ylig River, the former NWS meteorological observatory at Taguac, Anderson Air Force Base, and Naval Air Station Tiyan (Fig. 3), the latter two stations having the longest periods of record (Lander and Guard, 2003). Mean annual rainfall at the various locations gauged on Guam ranges from 84 to 116 inches (213–295 cm) per year (Johnson, 2012), with the wettest areas in the southern mountains, and the driest areas at

scattered points along the west coast (Lander and Guard, 2003). Inter-annual rainfall on Guam is strongly influenced by ENSO cycles, with droughts tending to occur in the winter and spring seasons following an El Niño event (Lander, 1994).

As noted, Guam is divided into two discrete petrological and geomorphological units (Figs. 4 and 5): (1) southern Guam, which has low permeability volcanic terrain drained by numerous perennial streams and (2) northern Guam, which is an elevated limestone plateau of high permeability that lacks flowing surface watercourses but contains large subsurface aquifers (Johnson, 2012). In this regard, the island functions as two disparate units in regard to its hydrological response to precipitation inputs, with volcanic southern Guam being a surface water sector, and limestone northern Guam being a groundwater sector.

In southern Guam, streamflow data are available from 19 USGS stream gauging stations with periods of record extending from 1951 to the present, although none of these gauges have continuous records for this entire period, and only two of the gauges that have >35 years of record are not affected by upstream diversions (Keener et al., 2012; Heitz and Khosrowpanah, 2015). This gauging data indicates a strong correlation and in-phase tracking between annual rainfall and stream discharge in southern Guam, although the relationship is not strictly linear. Maximum streamflow peaks in an average year strongly match maximum median rainfall, which occurs in September, whereas minimum stream flows have a lag, occurring in April, about 1 month after the normal annual rainfall minimum (Lander, 1994). This data clearly demonstrates a relationship between meteorological and hydrological drought on Guam, and also suggests that the average return interval for severe droughts may be close to 10 years, with severe droughts and correspondingly reduced stream flows having occurred in 1966, 1979, 1983 and 1998 (van der Brug, 1986; Polhemus, 2017).

Recharge rates for Guam's aquifers were investigated by Johnson (2012), who found that under drought conditions the recharge rate was 32% lower than mean baseline recharge. Based on analysis of monitoring well data, water levels in the aquifer during a typical year run 180 degrees out of phase with annual precipitation cycle (Lander, 1994), usually peaking in February, 6 months after the average maximum rainfall is received in September. There is thus a significant lag time between when rainfall occurs and when it actually enters the water table, indicating that it may take up to half a year to initiate aquifer recovery following a period of drought or over-utilization. Therefore, although stream total flows (which include surface runoff) closely track the temporal variation in rainfall, perennial stream base flows (which consist only of aquifer discharge) may run out of phase with precipitation inputs by several months.

The volcanic southern portion of Guam has 17 major watershed units (Fig. 6) containing 100 freshwater streams (if named tributaries are counted) within 46 catchments, constituting the vast majority of the streams found in the Mariana Islands. The constituent watersheds vary greatly in size, from the large and well-integrated Talofoto catchment that drains 28 miles² (73 km²) in the center of southern Guam, to the numerous short, relatively linear catchments such as Cette, Umatac and Geus along the southwest coast, which drain the steep seaward slopes of the southern mountains. In addition, the flat northern limestone plateau of Guam has no defined surface drainage channels, with water percolating into caves and emerging as springs near the coast.

Guam's native stream biota includes a moderately diverse array of fishes, prawns, molluscs and insects, although many of these groups are still inadequately studied. Information regarding Guam's freshwater fishes is fragmented, and no good compendium of records regarding their distribution or ecology has been published. Information is similarly fragmentary for freshwater molluscs and insects. By contrast, the local freshwater crustacean assemblage is well characterized, and has been the subject of ecological study (Leberer and Nelson, 2001).

Based on the checklist of Meyers and Donaldson (2003), supplemented by data from Walsh et al. (2014) and unpublished data supplied by the Guam Division of Aquatic and Wildlife Resources (Tibbatts, in litt.), a total of 32 species of native fishes are known to occur in stream habitats on Guam. The majority of these, consisting of 22 species, are itinerant marine-breeding taxa which enter estuaries, and may also penetrate a short distance up slow-moving stream terminal reaches to varying degrees, usually stopping when they encounter swifter water flowing over rocky substrates. This euryhaline assemblage includes taxa such as the Indo-Pacific tarpon (*Megalops cyprinoides*), mangrove red snapper (*Lutjanus argentimaculatus*), and several species of mullet (*Crenimugil seheli*, *Ellechlone vaigiensis*, *Moolgarda engeli*, and *Neomyxus leuciscus*) which are important food and sport fishes. Also present are certain morphologically specialized fishes, such as the narrow-lined pufferfish (*Arothron manilensis*), the bearded eel goby (*Taenioides limicola*), the feathered river garfish (*Zenarchopterus dispar*), and several species of pipefishes (*Microphis brachyurus*, *Microphis leiaspis*). Species in a few of these marine genera, notably flagtails (*Kuhlia* sp.) and eels (*Anguilla* sp.) may penetrate upstream well beyond the estuaries, dispersing through rocky midreaches until being stopped by the first major waterfall (Figs. 6 and 7). Anguillid eels in particular often preferentially inhabit deep plunge pools at the bases of waterfalls.

In addition, there are 10 additional species of gobies (Gobiidae) and sleepers (Eleotridae) on Guam whose adults live and breed in freshwater (Walsh et al., 2014). All of these species are amphidromous, with a marine planktonic larval stage and post-larvae migrating back into freshwaters, where the adult stages live and reproduce; as such, their life cycle still requires a link to marine habitats (Watson, 1991, 1992). Among the 8 goby species represented, 4 are largely confined to estuaries and lower-gradient stream terminal reaches, including the bandfin mangrove goby (*Mugilogobius cavifrons*), the speckled goby (*Redigobius bikolanus*), the spotfin river goby (*Awaous ocellaris*) and an apparently undescribed species of *Stenogobius*. The remaining 4 goby species can be found further upstream through more swiftly flowing midreach habitats with rocky beds. The upstream limit for the Mariana goby (*Awaous guamensis*) generally occurs at the first major waterfall barrier, but the red-tailed goby (*Sicyopterus lagocephalus*), the dwarf goby (*Stiphodon percnopterygionus*), and a potentially undescribed belted goby in the genus *Sicyopus* are capable of surmounting such barriers to enter headwater reaches. These latter species in the subfamily Sicydiinae can form their pelvic fins into a "pelvic disk," which functions as the equivalent of a suction cup, allowing them to inch up wet vertical rock faces, and thus reach considerable elevations above the sea (Keith et al., 1999). Among the sleepers, the dusky sleeper (*Eleotris fusca*) is a species of

Fig. 7 Tarzan Falls, on the upper Ylig River, is typical of the numerous waterfalls that interrupt stream profiles on Guam. Such falls represent the upper limit of habitat for itinerant marine fishes, but can be surmounted by certain gobies and shrimps which are adapted to exploit headwater reaches. The wet rock faces also provide specialized habitat for certain aquatic insects. Photo: Dan A. Polhemus.

estuaries and slow terminal reaches with muddy bottoms, in which they partially bury themselves. Another, currently undescribed species of cavernicolous sleeper is also known from water caves in the northern portion of Guam (Larson, 2001; Meyers and Donaldson, 2003).

As currently interpreted, the freshwater decapod crustacean fauna of Guam includes 7 species of small detritivorous shrimps in the family Atyidae (*Antecaridina lauensis*, *Atyoida pilipes*, *Atyopsis spinipes*, *Caridina brachydactyla*, *Caridina mertoni*, *Caridina typus*, *Halocaridinides trigonophthalma*), 2 larger species of omnivorous prawns in the family Palaemonidae (*Macrobrachium equidens*, *Macrobrachium lar*), and 3 species of crabs in the family Varunidae (*Orocvitta mollitia*, *Varuna litterata*, *Ptychognathus* sp.) (Leberer and Nelson, 2001; Leberer and Cai, 2003; Walsh et al., 2014; Tibbatts, 2017 in litt.). There is, however, lingering taxonomic uncertainty regarding the proper identification of some of these species, and the above list should thus be considered provisional. As with the gobiid fishes discussed previously, all of these crustaceans are amphidromous, with a freshwater adult stage and a marine pelagic larval stage, and the atyids can also climb waterfalls, just like sicydiine gobies, to colonize headwater reaches. The atyid genera appear to segregate on the basis of habitat, with *Atyoida pilipes* in swift, shallow riffles, and the assemblage of *Caridina* species inhabiting deeper water runs and pools. Flagtail fishes in the genus *Kuhlia* seem to exert significant predation pressure on these atyid shrimps, with lower densities and smaller sizes of shrimps in stream reaches where *Kuhlia* are present (Leberer and Nelson, 2001). In addition to these stream-dwelling species, an apparently undescribed *Halocaridinides* species has been reported from caves in northern Guam (Leberer and Cai, 2003).

The streams of Guam also support at least 16 species of freshwater prosobranch mollusks (Smith, 2003; Walsh et al., 2014), although the aquatic mollusk biota as a whole seems to be undersampled. This assemblage includes 11 species of amphidromous Neritidae in the genera *Clithon*, *Neritina*, *Neritodryas* and *Septaria*, all of which are herbivorous and widespread in the western Pacific. Adults of these species cling to midstream rocks and can often be found in swiftly flowing water. The remaining 5 species are obligate freshwater members of the Thiaridae, which are omnivorous and occur on sand or other softer substrates in standing or gently flowing water.

The aquatic insect biota of Guam is insufficiently investigated, and relatively comprehensive faunal assessments are available for only a few orders. The best-studied group are the dragonflies and damselflies (Odonata), with 14 species, including 1 archipelagic endemic species (*Anax piraticus*) and two endemic subspecies (*Agrionoptera insignis guamensis* and *Rhyothemis phyllis vitellina*), all of these also occurring on Saipan and Tinian. These local endemics tend to breed in standing water habitats rather than streams. The remaining dragonflies consist of widespread species that will exploit both stream pool habitats and ponds. Interestingly, Guam supports no endemic damselfly species (suborder Zygoptera), despite the fact that locally endemic species in this group are typical of a typical feature of islands as large and well-watered as Guam elsewhere in the Pacific. This anomaly is further highlighted by the presence of an endemic damselfly species on adjacent Rota (Polhemus et al., 2000).

A checklist of Guam's aquatic true bug (Heteroptera) biota has also been generated (Polhemus in litt.), and contains 13 species, of which a water strider (*Limnogonus lundbladi*), a shore bug (*Saldula guamensis*) and a toad bug (*Nerthra nervosa*) are currently considered endemic. Except for the above two orders, no other aquatic insect groups have been comprehensively tabulated for the island or are known to harbor endemic species there. Based on recent survey work across 12 sites representing varied habitats,

Englund (2011) reported 35 species of freshwater aquatic insects from Guam representing 6 orders. These included 11 species of Odonata, 9 species of Heteroptera, 10 species of flies (Diptera), and one species each of mayfly (Ephemeroptera), caddis fly (Trichoptera) and aquatic moth (Lepidoptera). A widespread diving beetle (*Eretes griseus*) has also been reported from the island (Miller, 2002). Based on all of the above information, it thus appears that the current stream insect biota of Guam consists of at least 41 species representing 7 orders, with 6 endemic taxa.

Island of Rota

Rota lies at 14°09'N, 145°13'E, and is the second largest island in the Marianas. Its western end of is dominated by the Sabana Plateau, or "Mt. Sabana," consisting of an irregular plateau measuring approximately 1300 ft. (400 m) in height and 4 miles² (10.4 km²) in area, rising to a highest summit at 1612 ft. (491 m) Mt. Manira. Largely comprised of limestone with some older volcanic outcrops, the plateau contains numerous caverns and is very porous in general. There are no long-term rainfall gauging records for the island, thus its hydrology is inadequately understood, but annual precipitation is likely to be about 80 inches, similar to adjacent Guam and Saipan. As on those latter islands, spring discharges exhibit a direct response to precipitation deficits, with the Matan Hanum and As Onan springs that constitute the major water supplies for Rota both exhibiting reduced flow volumes from April through June of the 1998 drought year (Carruth, 2005).

Rota is similar to northern Guam in possessing very few stream channels, intermittent or otherwise, due to the high permeability of its limestone bedrock (Davis, 1958). As a result, most rain falling at the upper elevations filters quickly into the substrate, leaving only ephemeral streams along its slopes. While the east, north and west sides of the plateau gradually drop off in a series of natural terraces, the southern slopes of the plateau are particularly steep, with vertical cliffs dropping precipitously to an area known as the Talakaya region, (Keel et al., 2007). Comprised of older volcanic substrate, the Talakaya region (Fig. 8) protrudes between two limestone formations lying both above and below (Randall, 1989). Spring water emerges at the limestone-basalt interface below the highly permeable Sabana Plateau (Fig. 8), providing the source for a set of perennial streams in this limited part of the island (Polhemus et al., 2000; Keel et al., 2007).

According to Camacho et al. (1997), stream flow is intermittent in most of the streams in this region, occurring primarily during periods of heavy rainfall. The one exception is Okgok Stream system (Fig. 8), which is considered the only true perennial stream on Rota. This catchment drains approximately 40% the Talakaya region, where highly weathered volcanic soils are exposed at the

Fig. 8 The watersheds of Rota, illustrating how stream channels are confined to the Talakaya region in the far south of the island. Only the Okgok Stream is perennial, with all the other channels shown supporting only intermittent flow during the wet season or after heavy rains.

Fig. 9 Sonson Water Cave, the primary source for the Okgok Stream system on Rota. Photo: Mike Richardson.

surface (Camacho et al., 1997). Approximately 0.87 mile (1.4 km) in length, Okgok Stream originates at a large artesian spring known as the Sonson Water Cave (Fig. 9), located at approximately 820 ft. (250 m) elevation. The vegetation along the headwater and midreach of Okgok stream consists primarily of mature, tall-canopied, native forest on limestone (Keel et al., 2007; US Forest Service, in litt.), which provides an extensive canopy cover and shading. The terminal reach has riparian vegetation consisting largely of cultivars such as banana, breadfruit, bamboo and coconut (Camacho et al., 1997).

Several of the Talakaya springs are used as the primary domestic water source for Rota, including Matan Hanum Spring, As Onon Spring, and most significantly the Sonson Water Cave (Polhemus et al., 2000; Berger et al., 2005; Keel et al., 2007). A concrete collection structure with associated piping has been built into the entrance of Sonson Water Cave (Fig. 9), and delivers approximately 2.7–3.8 million liters-per-day of water (1.8 Mgal/day) to Rota's municipal system (Stafford et al., 2005; Keel et al., 2007). At present, water captured from these springs exceeds demand, although periodic drought conditions can reduce the discharge from these springs in certain years. Under such conditions, dewatering of the Okgok Stream is entirely plausible without concomitant changes to water use and conservation (Keel et al., 2007). Indeed, (Berger et al., 2005) reported that water extraction from the springs other than the Sonson Water Cave already leaves many of the streams in the Talakaya region dry most of the year.

The most comprehensive study of Okgok Stream to date remains the work of Camacho et al. (1997), funded by the US Fish and Wildlife Service. This study characterized the aquatic macrofauna of the perennial Okgok Stream as well as several other intermittent streams found within the Talakaya region, and also assessed other biotic factors including canopy cover. These investigators reported the presence of four native fish species, consisting of the marine itinerant flagtail (*Kuhlia rupestris*) in the terminal reach below the first waterfall, with an eel (*Anguilla marmorata*), and two gobies (*Stiphodon elegans*, *Sicyopus leprurus*) inhabiting the swifter midreach waters further upstream. Three native species of shrimps were also recorded, consisting of one large palaemonid (*Macrobrachium lar*) and two much smaller atyids (*Atyoida pilipes*, *Caridina typus*), all of these again in faster flowing midreaches with rocky or gravel substrates, and lying above the first waterfall, which blocks the upstream migration of the predaceous flagtails. The native freshwater mollusk assemblage at Okgok Stream contained two species of thiarids (*Melanoides tuberculata*, *Thiara scabra*), but exhibited a surprising absence of amphidromous neritids, which are common and diverse on adjacent Guam.

The aquatic insect biota of Rota remains poorly known, and was not addressed by the surveys of Camacho et al. (1997). Subsequently, surveys by US Fish and Wildlife Service biologists determined that the Okgok Stream and its tributaries are the single known locality in the world for the Rota blue damselfly (*Ischnura luta*), the only single-island endemic stream-breeding invertebrate species in the Mariana Islands (Polhemus et al., 2000). In addition to *I. luta*, one further widespread damselfly, *Ischnura aurora*, is also recorded from Rota (Liefstinck, 1962), although this species is also capable of breeding in ponds and wetlands, unlike *I. luta* which appears to be an obligate stream-breeder, and due to its limited range has been protected under the US Endangered Species Act. Other species of aquatic insects are undoubtedly present on Rota, but further survey work is needed to characterize this biota.

Although the study of Camacho et al. (1997) concluded that the aquatic fauna of Rota was less diverse than that of many other areas studied within the Western Pacific, including Guam, the overall assemblage in the Okgok Stream is in fact considerably richer than that reported from Saipan, the only other island in the Marianas with a perennial stream. This further highlights the relatively impoverished faunal assemblage present in Mariana Island streams as a whole, due to their limited spatial extent and isolation from source areas.

Island of Saipan

Saipan lies at 15°11'N, 145°45'E, and represents a formerly submerged and secondarily uplifted volcanic island formed at the margin the Pacific Plate. Approximately 95% of the island's surface geology consists of limestone, overlying thinner layers of sandstone, conglomerate and breccia sitting atop an andesitic volcanic core (Izuka and Ewart, 1995). A ridge of limestone runs through the middle of the northern two-thirds of the island, forming large stretches of mostly east-facing cliff line, with 1556 ft. (474 m) Mount Tagpochau, the highest point on the island, occurring within this ridgeline near the island's center. Similar to Guam and Rota, annual rainfall on Saipan averages approximately 80 inches (203 cm) per year, with 67% of this arriving during the wet season which extends from July to November (Carruth, 2003; Lander, 2004). Intra-island variation in rainfall appears to span a relatively narrow range, from 75 inches (190 cm) annually at the airport to 90 inches (229 cm) annually at Capitol Hill (Lander, 2004), with no pronounced leeward versus windward dichotomy. The preceding numbers must be treated as approximations, because there is ambiguity as to the locations of the rain gauges involved over time, and their data are thus not precisely representative of any particular site. In addition, no single location has a 30-year record generally deemed necessary to establish an accurate rainfall climatology. Despite its abundant rainfall, Saipan exhibits relatively few stream channels due to the high permeability of its limestone surface, and most of the streams present are intermittent (Davis, 1958), although some in the Achugao and Kagman watershed units (Fig. 10) may retain nearly permanent pools (McCagan et al., 2008). In this regard it is similar to Rota and the northern portion of Guam.

Talufofo Stream, on the northeast side of Saipan (Fig. 10), is the only stream with true perennially flowing reaches on the island (Izuka and Ewart, 1995), having a drainage basin that encompasses a roughly triangular-shaped area of approximately 1.6 miles² (4.1 km²). The Talufofo Stream catchment is branching and dendritic, with three principal tributaries, consisting of the North, Middle, and South Forks. Like many streams on southern Guam and the Okgok Stream on Rota, base flow in the Talufofo basin headwaters originates as perennial groundwater discharging from springs which emerge at points where a contact between the porous limestone formations and less permeable underlying volcanic formations is exposed, generally at elevations between 400 and 500 ft. (122 and 152 m) (Izuka and Ewart, 1995). These small headwater reach channels are surrounded by grass-covered savanna slopes, while the lower half of the basin along the midreaches and terminal reach is covered by a mixed-secondary forest (Fig. 11). The three forks converge at a point about 0.4 mile (0.64 km) from the coast, where the underlying substrate transitions to highly permeable limestone, causing streamflow to become seasonally intermittent from this point to the coast (Izuka and Ewart, 1995). As such, the Talufofo may be considered a naturally interrupted stream according to the ecosystem classification of Polhemus et al. (1992). According to measurements taken in the mid-1990s, the sum of the average flows at the Middle Fork and South Fork gaging stations, plus an estimate of the average flow at a point along the lower midreach of the North Fork, was equivalent to about 1.91 million gallons of water per day (MPG), or 7.2 million liters per day (MLD) (Izuka and Ewart, 1995).

The most comprehensive hydrological study of Talufofo Stream to date remains the work of Izuka and Ewart (1995), conducted during the mid-1990s and commissioned by the CNMI government to assess the feasibility of using the stream's water to supplement Saipan's municipal water supply. The island of Saipan has, since the drought of 1983, endured persistent water supply problems, with the shallow wells which supply most domestic uses becoming brackish due to the island's porous geology and shallow freshwater lens (van der Brug, 1986; Carruth, 2003, 2005). During their analysis, Izuka and Ewart (1995), examined flow characteristics of Talufofo stream, its chemistry, and the stream's origin and interaction with the underlying geology. Based upon streamflow and water-chemistry data, the study indicated that discharge from springs was in hydraulic connection with the limestone aquifer near the headwaters of the Talufofo Stream basin. Most pertinently at the time of the study, this meant that pumping from wells in the limestone substrate at the headwaters of Talufofo Stream catchment would likely decrease spring flow into Talufofo Stream itself—essentially negating the rationale for taking water out of the stream if pumping at the aquifer source were conducted concurrently. The study provided very little other information regarding the health or condition of Talufofo Stream, and there seem to be no subsequent studies assessing its condition.

On Saipan, there are also numerous other small springs originating from elevated limestone aquifers in the central uplands of the island, but few are monitored. Discharge was measured at Donni Spring from 1952 to 1954, and again from 1969 to 1983 using a continuous-recording gauge. During the drought of 1982–1983, flow at this spring registered only 69% of normal (van der Brug, 1986), clearly demonstrating the close coupling between precipitation inputs and groundwater discharge, similar to that seen on southern Guam. Based on the current fragmentary data, it is not possible to quantitatively evaluate the effects of the subsequent 1998 or 2016 El Niño droughts on Saipan's surface hydrology.

Very little work has been done on the freshwater biota of Saipan or the other Mariana Islands outside of Guam and Rota (James et al., 2010), and no endemic freshwater species are known to occur on the island. Based on collections made from a limited number of sites on Saipan, with identifications validated through use of molecular techniques (James et al., 2010), 8 species of native freshwater fishes occur (McCagan et al., 2008), including the estuarine Indo-Pacific tarpon (*Megalops cyprinoides*), and the amphidromous green riffle goby (*Stiphodon elegans*) and spine cheek gudgeon (*Eleotris acanthopoma*), the latter two inhabiting limnetic waters. Both the *Stiphodon* and *Eleotris* species are not recorded in current lists from nearby Guam, and it is possible that some taxonomic confusion exists regarding the identities currently assigned to species in these genera across the Marianas as a whole.

In regard to native aquatic invertebrates, Saipan's inland waters harbor 3 native shrimps (*Caridina typus*, *Palaemon concinnus*, *Macrobrachium lar*), and 9 widespread damselfly and dragonfly species (*Ischnura aurora*, *Agriocnemis femina*, *Anaciaeschna jaspidea*, *Diplacodes bipunctata*, *Tholymis tillarga*, *Pantala flavescens*, *Rhythemis regia*, *Chalcoptilon*, *Tramea transmarina*, *euryhale*, *Macrodiplax cora*), as well as the two archipelagic endemic dragonfly taxa, the species *Anax piraticus* and subspecies *Agrioptera insignis guamensis*,

Fig. 10 The major watershed units of Saipan. Only the labeled Talafofo Stream is perennial (although naturally interrupted), with all the other channels shown supporting only intermittent flow during the wet season or after heavy rain events.

which also occur on Guam (McCagan et al., 2008; Lieftinck, 1962). Although some of the shrimp and dragonfly species will breed in streams, many of the latter are more typically found associated with ponds or small wetlands. Other stream-associated shrimps, molluscs and aquatic insect species undoubtedly occur on Saipan, but proper surveys have not been undertaken to characterize this biota.

Conservation

Based on radiocarbon dates from archeological sites in Saipan, it appears that human habitation in the Mariana Islands dates back at least 3500 years (Spoehr, 1955; Fitzpatrick, 2018), this being the oldest evidence for prehistoric settlement in all of Micronesia.

Fig. 11 Riparian ecosystems of Saipan.

These early inhabitants had a significant effect on the native vegetation of the islands over three millennia through the agencies of fire and forest clearing for agriculture (Muller-Dombois and Fosberg, 1998), particularly after A.D. 900 when the population appears to have increased substantially (Fitzpatrick, 2018), and this in turn undoubtedly had some impact on runoff patterns and stream flow regimes. No records exist of this, however, and only fragmentary descriptions are available of the nature of the landscape even at the time of Spanish colonization (Muller-Dombois and Fosberg, 1998), which produced additional ecological disruption from European-introduced crops and ungulates. In the 20th century, forest clearing and combat during World War II further served to disrupt the landscape, obscuring its original patterns of vegetation, and creating denuded badlands in areas such as southern Guam.

As such, it is possible to make only tentative inferences as to how Marianas streams functioned under their original, intact condition prior to the arrival of the Chamorro people. Based on more intact systems elsewhere in the insular Pacific, it is likely that in their original state Marianas streams may have been bordered by closed canopy riparian forests in their headwaters, trending to mixed open canopy forest at lower elevations, possibly dominated by betel nut palms (*Areca catechu*) (Muller-Dombois and Fosberg, 1998). The stream channels probably exhibited high bank stability, waters flowing in them had lower turbidity, and there was a lesser degree of in-stream algal growth, allowing better oxygenation and more favorable habitat for native aquatic species.

Streams were used by the early Chamorro as sources of fresh drinking water and to a limited extent for irrigation of various traditional crops such as taro, rice, ginger, yams, breadfruit, and bananas, although there is little evidence of extensive ditching or rice terracing (Hunter-Anderson et al., 1995). Later, during the Spanish colonial period from the 1565 to 1898, stream waters continued to be used for the irrigation of newly introduced crops including corn and sugar, and during the period of Japanese occupation during World War II rice cultivation expanded to support the military presence (Rogers, 1995). Even so, stream diversions on Guam have historically been limited, due to the absence of a plantation economy, with most of these diversions taking small volumes of water and occurring near headwater springs (Ward et al., 1965). At the present time, Guam derives 80% of its municipal drinking water from about 180 groundwater wells, predominantly located in the northern half of the island (Gingerich, 2003). The remaining 20% of water supplies are derived from reservoirs in southern Guam, primarily the Fena Valley

Reservoir, the largest on the island, which also incorporates diversions from the Almagosa and Bona springs (Ward et al., 1965; Gingerich, 2003). As such, many of Guam's perennial streams still flow unimpeded to the sea.

Current threats to watershed integrity on Guam, and elsewhere in the Marianas, include chronic wildland fire and feral ungulate disturbance in the headwater areas, associated sedimentation from lands degraded by fire or ungulates, channelization near the coast in areas of urban or suburban development, and pollution from scattered small point sources such as carelessly discarded paints or oil. The most obvious and recurrent of these disturbances is wildland fire. The frequency of fires on Guam was analyzed by Minton (2006) for the period from 1979 to 2000, with the island averaging 730 fires per year over this period, burning an annual average of 4800 acres (1942 ha). On both Guam and the islands of the CNMI, fires were concentrated in the dry season months, with over 95% of ignitions occurring between January and June. Annual fire variability was also strongly correlated with rainfall, in regard to both the number of fires and fire sizes (Minton, 2006). Years immediately following ENSO events displayed a significantly higher incidence of fire, with the number of fires more than doubling and the number of acres burned more than tripling in comparison to non-ENSO years, illustrating a link between El Niño-mediated droughts and subsequent fire frequency and size. The translated ecological effects of increased wildland fire on Guam include spread of invasive, non-native grasses which promote additional fire and loss of remaining forests, as well as higher rates of erosion from the burned areas, resulting in increased sediment influx into stream channels. In particular, Minton (2006) documented a six-fold increase in erosion rates from recently burned savannahs in the Piti-Asan watershed. Such effects are also persistent, with the same study noting a two-fold increase in sedimentation 2 years later in comparison to unburned areas, despite a certain degree of vegetative recovery. Drought and fire thus work in tandem to alter watershed vegetative cover and increase stream channel sedimentation. Because nearly all wildland fires in the Marianas are anthropogenic in origin, as a result of arson, carelessly discarded cigarettes, or hunters seeking to provide new grass shoots for introduced deer or to drive out pigs, this source of watershed stress is potentially amenable to socially-based management solutions, although these have to date had little success.

Another significant threat to the biological integrity of Mariana Islands streams is the continuing introduction and establishment of invasive, non-native aquatic species (Walsh et al., 2014). Freshwater ecosystems on Guam now support at least 13 invasive fishes (Walsh et al., 2014; Tibbatts, in litt.), including large predators such as striped snakehead (*Channa striata*), Mozambique tilapia (*Oreochromis mossambicus*), and other cichlids such as the oscar (*Astronotus ocellatus*) and butterfly peacock bass (*Cichla ocellaris*) that consume native fish species; various mosquitofish, guppies and swordtails (*Gambusia affinis*, *Poecilia reticulata*, *Xiphophorus helleri*) that have adverse effects on native aquatic insect species; and common carp (*Cyprinus carpio*) that overturn substrate and degrade water quality. Eight of these species, including the Mozambique tilapia, the mosquitofish, and the sailfin molly, have been confirmed on Saipan as well (McCagan et al., 2008; James et al., 2010).

In addition, at least 20 species of non-native amphibians and reptiles are now established in the inland waters of the Guam (Walsh et al., 2014; Tibbatts, 2017 in litt.), including the cane toad (*Rhinella marina*), 7 frog species that can potentially breed in flowing streams (*Fejervarya cancrivora*, *Fejervarya limnocharis*, *Hylarana guentheri*, *Kaloula pulchra*, *Litoria fallax*, *Pelophylax nigromaculatus*, *Pseudacris regilla*), the Chinese softshell turtle (*Pelodiscus sinensis*), and the red-eared slider turtle (*Trachemys scripta elegans*), the first and last listed species having also reached Saipan. At least 4 introduced aquatic mollusk species are also present on Guam or Saipan (McCagan et al., 2008; Tibbatts, 2017 in litt.), including two large-sized apple snail species (*Pila conica*, *Pomacea canaliculata*) that are considered agricultural pests impacting traditional taro cultivation. Finally, at least 8 invasive aquatic plants have become established on Guam (Tibbatts, 2017 in litt.), including major aquatic weeds such as water hyacinth (*Eichornia crassipes*), water lettuce (*Pistia stratiotes*), and duckweed (*Lemna minor*) which can rapidly cover the surfaces of stream pools or other slow-flowing reaches, significantly affecting sunlight penetration and nutrient cycling.

Most of these non-native species are capable of establishing themselves in the limnetic terminal reaches or midreaches of streams, and some such as tilapia will also invade mixohaline estuaries, although their distribution on the islands is variable since their dispersal across drainage divides requires human assistance. Certain watersheds on Guam, such as Agana and Talafofo (Fig. 6), now contain large numbers of such species, while in other smaller, more remote watersheds they are still essentially absent (Tibbatts, in litt.). Such aquatic invasive species also do not appear to be as well-established in the few streams on Rota and Saipan, and measures should be taken to prevent their future importation, establishment or spread.

Future Scenarios

Given the strong linkages between precipitation and Marianas stream discharges previously described, any future assessment of the integrity of these ecosystems must take projected climate change into account. As an ancillary product to the National Climate Assessment effort, a Pacific Islands Regional Climate Assessment (PIRCA) was produced in 2012 (Keener et al., 2012). This document, incorporating the contributions of nearly 100 independent experts, evaluated the state of knowledge related to climate drivers, impacts, and adaptive capacity within three sub-regions of the Pacific, including the Western North Pacific which includes the Mariana Islands. The findings bearing on freshwater systems are summarized below, and those wishing greater detail should consult the PIRCA, which treats these subjects in greater depth.

Depending on representative concentration pathway (RCP) model employed, CO₂ concentrations are projected to reach levels between 420 and 935 parts per million (ppm) by the end of the century (IPCC, 2014). As of May 2019 atmospheric CO₂ stood at 413 ppm, an increase of over 93 ppm from when standardized readings first began to be collected in the late 1950s at the Mauna Loa Observatory in Hawaii. The accumulation of carbon dioxide and other greenhouse gases in the atmosphere has led to warming

of both the atmosphere and the oceans due to the enhanced greenhouse effect. Temperature projections from both the Intergovernmental Panel on Climate Change's (IPCC) Fourth Assessment Report (Parry et al., 2007) and the second national assessment (US Global Change Research Program, 2014) indicate continued warming into the foreseeable future, with global average surface temperature projected to increase 1.2–6.4°C by 2100, with best recent estimates placing the range between 1.2 and 3.2°C (IPCC, 2014; Gattuso et al., 2015). Average tropical sea surface temperature (SST) is expected to increase by 50–80% of the average rate of atmospheric change (Guinotte et al., 2003). Therefore, average sea temperatures in the Marianas will probably increase by 1–2°C over the course of this century, providing additional atmospheric water vapor. Such increases in ocean and air temperature are related to changes in atmospheric circulation patterns that may result in more severe periods of drought and more markedly episodic high precipitation events, a trend already observed in Hawaii (Chu et al., 2009) where long-term stream and precipitation gauging records depict clear declines in precipitation and stream base flow over the past century, but high variations in stream total flow (Oki, 2004).

Global circulation models have projected that under a global warming regime fewer tropical storms will form, due to increased propensity for wind shear in high SST environments (Nolan and Rappin, 2008), but that those storms which do form will be more intense (Bengtsson et al., 2007), a prediction that has been borne out by recent storms of record intensity, such as Typhoon Yutu, that have affected the Marianas (and many other tropical areas of the world) in recent years. Modeling of the hydrological cycle under a regime of warming climate results in a projection of a 27% increase in atmospheric water vapor in the tropics over the next 100 years. Because this is also coupled with a longer residence time of water in the atmosphere, this increase in atmospheric water vapor does not necessarily result a marked increase in precipitation; instead, the moister atmosphere simply becomes capable of retaining greater heat content, thereby spawning stronger storms (Bengtsson et al., 2007). Global circulation models therefore project an increase in the proportion of extreme weather events in the most severe categories (Webster et al., 2005; IPCC, 2014), with the associated potential for extreme precipitation events, and thus higher and more acute discharge peaks, and more severe flash flooding in Marianas stream catchments.

The intensity and frequency of days of extreme heat are also projected with high confidence to increase over the course of the 21st century across the Mariana Islands. The CMIP3 model ensemble under several emissions scenarios produced projections that annual surface air temperatures (SATs) for the Western North Pacific sector containing the Mariana Islands, will range from 1.1 to 1.3°F higher by 2030, 1.9 to 2.6°F higher by 2055, and 2.7 to 5.1°F higher by 2090 (Australian Bureau of Meteorology and CSIRO, 2011). A subsequent analysis using the CMIP4 model ensemble further supported these projections (Parry et al., 2007). More recently, Polhemus (2017) presented model runs from the new CMIP5 ensemble under RCP 8.5, which generated somewhat revised projections, with SATs in the Western North Pacific ranging from 0.4 to 2.0°F higher by 2030, 2.0 to 3.5°F higher by 2055, and 4.8 to 6.4°F higher by 2090. Although there is some variability in the results of these different model suites, the underlying conclusion of steadily rising future temperatures is consistently the same (see Appendix 1).

For precipitation, projections of future trends are less well constrained than those for mean annual temperature. Although some initial approaches to climate model downscaling are being undertaken for the Marianas, such efforts are still incipient, and the results provisional. Any projections therefore have considerable uncertainty, which can only be reduced by future improvements in regional model input parameters. An initial run with the current CMIP5 ensemble under RCP 8.5 presented by Polhemus (2017) produces projections that indicate average daily precipitation will exhibit a 12–13% increase in the Marianas sector as a whole by 2100 (see Appendix 1). These projections do not, however, provide any information as to potential changes in the temporal distribution of rainfall within any given year.

These projected changes in ocean and atmospheric temperature, precipitation patterns, and tropical storm intensity over the coming decades all have significant implications for the future state of perennial stream ecosystems in the Marianas. The warming projected during the next 50 to 100 years will create heat-related stress for human communities and agriculture, putting additional loads on water supply systems. The increased heat will also further promote wildland fire, thereby further degrading stream catchments and increasing sedimentation, and creating increased extinction risk for native plant and animal species (Urban, 2015). Seasonal changes in precipitation patterns, coupled with increased temperature and evapotranspiration, also have the potential for widespread and significant impacts to water resources and agriculture, which will create both societal and ecological challenges. Based on historical and projected patterns of land-cover change in the Marianas, often associated with fire during drier periods, impacts from invasive species and human development are likely to amplify the adverse effects of climate change on freshwater habitats and their associated species, unless informed policy and adequate management strategies are proactively implemented.

A limited suite of conservation efforts are currently underway in the form of evolving policy and laws, restoration and management, education and outreach, and creation of protected natural reserves, but all these have to date had only a modest impact as far as shielding Marianas streams from further declines in functionality (Englund, 2011). As such, perennial streams Mariana Islands currently continue to suffer from degradation of surrounding habitats, and will continue to do so in the absence of more effective land management practices, particularly on Guam (Taborosi, 2013).

Appendix 1

Supporting climate model data for future scenarios (from Polhemus, 2017).

The data provided below represent preliminary outputs from the CMIP5 ensemble of 36 dynamical climate models. Each CMIP5 model was interpolated horizontally to 1 degree by 1 degree grids, over a time series beginning in 2010 and ending at 2099. Those

regridged data were then interpolated to each island point using the bilinear interpolation method. Ten years are chosen as the time slice to represent the specific year, e.g., the mean value from 2025 to 2034 to represent the value of 2030, the mean value from 2050 to 2059 to represent the value of 2055, and the mean value from 2090 to 2099 to represent the value of 2100.

Minimum and maximum projected air temperature envelope bounds of each of the above time steps were calculated from data representing a subset of the CMIP5 ensemble, using only those models that project t-min and t-max over the three time windows indicated above. These data represent the average value of t-min and t-max taken over the sampling windows, and thus are not strictly the t-min and t-max of the daily average temperature, and will have a slightly broader variance from central tendency, but are sufficient to indicate approximate envelopes of uncertainty.

The present-day reference values were calculated as averages for period 1995–2004, using the full CMIP5 model ensemble.

Abstract

The majority of flowing waterbodies throughout the world can be considered intermittent rivers or ephemeral streams (IRES) because at some point in time and space they stop flowing or dry. Despite their global abundance, less is known about this biome compared to perennial—permanently flowing—rivers. However, a recent surge in research has dramatically improved our understanding of how IRES function and what types of biodiversity and ecosystem services they support. A cycle of terrestrial-aquatic habitat conditions caused by the periodic drying and rewetting creates a high temporal dynamic in the biogeochemistry, biodiversity, and ecosystem services of IRES. Vast amounts of accumulated sediment, organic matter and organisms can be transported from IRES downstream to larger rivers or lakes, contributing to the global C cycle. The mosaic of aquatic and terrestrial habitats along IRES hosts high biodiversity including microorganisms, plants, invertebrates, reptiles, and mammals, with specialized strategies to resist to or recover from changes in habitat conditions. Although IRES provide a broad range of ecosystem services including provision of fresh water and cultural enrichment, there is a continued struggle to protect this dynamic and threatened biome.

What Are Intermittent Rivers and Ephemeral Streams?

Hydrologically Diverse and Globally Abundant

Intermittent rivers and ephemeral streams (IRES) refer to all flowing waters that cease flow and/or dry completely at some point along their course (Datry et al., 2017, Fig. 1). Arguably the world's most widespread type of flowing water (Larned et al., 2010; Datry et al., 2018a), IRES range from small ephemeral streams that flow for a few days after heavy rain to large intermittent rivers that recede to isolated pools but might not dry completely. Many local names for IRES exist throughout the world such as temporary rivers, winterbournes, wadis, arroyos and ramblas (e.g., Steward et al., 2012), highlighting the diversity and cultural importance of this biome to people living in their catchments.

IRES occur on all continents, including Antarctica (Larned et al., 2010; Steward et al., 2012). IRES are dominant features of hyper-arid, arid, semi-arid, and dry-subhumid regions, which represent a third to half of the Earth's land surfaces (Tooth, 2000; Whitford, 2002; Millennial Ecosystem Assessment, 2005, Fig. 1). As examples of their abundance, 70% of rivers are classified as intermittent in Australia (Sheldon et al., 2010), 66–94% of river lengths in Southwestern United States (i.e., Arizona, New Mexico, Utah, Nevada, Colorado, California; Levick et al., 2008) are IRES, and they are found across Mediterranean, temperate, humid, boreal, alpine and polar regions (Sabater and Tockner, 2009; Bonada and Resh, 2013; Leigh et al., 2015). Virtually every river network includes IRES, notably because the dense network of headwaters, which can make up >70% of the total river network length, is typically intermittent (Lowe and Likens, 2005; Meyer et al., 2007; Fritz et al., 2013; Grill et al., 2019).

Fig. 1 Different types of IRES from across the world: (A) unnamed karstic stream, West Coast, South Island, New Zealand, (B) Río Seco, Chaco, Bolivia, (C) Asse River, Provence, France, (D) unnamed gravel-bed stream, West Coast, South Island, New Zealand, (E) unnamed stream, Altiplano, Bolivia, (F) Chaki Mayu, Amazonia, Bolivia, (G) Clauge, Jura, France, (H) Calavon River, Provence, France, and (I) Hozgarganta River, Andalucía, Spain. The map represents five categories of the percentage of dry riverbeds over the total river surface per COSCAT (a global segmentation scheme of coasts and river catchments; [Meybeck et al., 2006](#)). Dry riverbeds have been estimated as the river surface area dry all year long from models developed in [Raymond et al. \(2013\)](#). These estimates represent the only available global estimates and may over-represent dry riverbeds at higher latitudes. Photo credits: Thibault Datry (A–F), Bertrand Launay (G and H), and Núria Bonada (I).

Three-in-One: IRES Contribute to Lotic, Lentic, and Terrestrial Dynamics

IRES are dynamic shifting habitat mosaics of flowing, non-flowing and dry patches ([Fig. 2](#)), the extent and connectivity of which constantly vary across drainage basins in response to river discharge and groundwater levels ([Stanley et al., 1997](#); [Jaeger et al., 2014](#); [Datry et al., 2016a](#)). To account for this dynamism in habitat types, concepts from lotic (aquatic flowing), lentic (aquatic non-flowing) and terrestrial ecology are used to understand these ecosystems ([Datry et al., 2014b](#)). In general, river networks are an aquatic continuum in a terrestrial matrix and therefore meta-ecosystems linked by lateral (terrestrial to aquatic), vertical (from

Fig. 2 Alternating lotic (flowing) (A), lentic (non-flowing) (B) and terrestrial (dry) phases (C) in an intermittent river of France (Calavon River). Below each photo is a graphical depiction of the likely vertical and longitudinal and lateral dimensions of each flow-state. Gray box below stream channel (vertical dimension) represents the hyporheic zone that may remain saturated even during surface drying events. Photo credits: Bertrand Launay.

the surface to the subsurface) and longitudinal (from upstream to downstream) flow of matter and energy (Battin et al., 2009). In IRES, the mosaic of lotic, lentic, and terrestrial environments creates patches of sub-ecosystems that interact differently among each other and with the terrestrial matrix. The flows of matter and energy, which affect biogeochemical cycles and ecosystem functioning, change with alternating dry and wet phases and depending on network position (Datry et al., 2017; von Schiller et al., 2017). Lateral flows of organisms and resources with the surrounding terrestrial habitat are likely to be enhanced during the dry phase when terrestrial organisms colonize dry riverbeds. However, little is known about the spatiotemporal variability of these flows and their effect on biogeochemical cycles and ecosystem functioning at the entire river network scale.

Biogeochemical Dynamics in Intermittent Rivers and Ephemeral Streams

Streams and rivers transport a variety of dissolved and particulate compounds, such as nutrients (e.g., nitrogen, phosphorus) and organic matter, which constitute bases for stream food webs and ecosystem functioning (Meybeck, 1982). The biogeochemical cycles, resulting from the input, removal, transformation, production, and export of these compounds, are generally controlled by factors such as humidity, temperature, flow velocity (Shumilova et al., 2019). In response to alternating lotic, lentic, and terrestrial phases over time and geographic location, IRES have temporally and spatially discontinuous biogeochemical processes with pulsed nutrient and OM inputs, processing, and transport events (von Schiller et al., 2017).

Organic matter processing (i.e., decomposition) and transport are typically halted while riverbeds are dry due to reduced activity of microorganisms (Corti et al., 2011; Sabater et al., 2016) and loss of hydrological connectivity, respectively. However, stream

biofilms associated with dry sediments may continue processing organic matter (Timoner et al., 2012) and the activity of some anaerobic microbes may lead to changing levels of stream nutrients, such as nitrogen (Austin and Strauss, 2011; Merbt et al., 2016) on dry riverbeds. Colonization of the dry riverbed by terrestrial animals (e.g., insects, mammals) and plants may also modify organic matter and nutrients dynamics through imports of terrestrial compounds or utilization of the instream resources.

In pools that may remain along the dry riverbed matrix, the accumulation of organic matter combined with high respiration rates and the lack of oxygen when air temperature rises can create anaerobic or hypoxic conditions. Organic matter usually accumulates in the form of leaf litter from riparian trees, as algae growth in pools with low canopy cover, or both, and rates of decomposition are low (Corti et al., 2011). The nutrient balance is also modified due to denitrification processes, with nitrates usually decreasing and phosphate and ammonium contents increasing (von Schiller et al., 2011). Very low oxygenation at the later stages of pool drying may also lead to methane production (Gómez-Gener et al., 2016).

Flow resumption usually leads to pulses of organic matter and nutrients that are imported from the riparian zone into the stream and from upstream to downstream as the lateral and longitudinal hydrological connectivity is restored. Pulses of decomposition may then occur downstream where massive amounts of organic matter accumulates (Corti and Datry, 2012; Datry et al., 2018b).

Organic matter decomposition and microbial activity are the main drivers of carbon dioxide emissions from river ecosystems. CO₂ emissions from IRES are similar to those of their perennial counterparts during the flowing phase, globally estimated to be 1.75 g CO₂ m⁻² day⁻¹ (Raymond et al., 2013). However, these estimates do not take into account the rewetting and dry phases during which CO₂ emissions may greatly exceed those during flowing phases. Whereas dry sediments can release up to 67.5 g CO₂ m⁻² day⁻¹ (Gómez-Gener et al., 2016), pulses of decomposition and sediment respiration during rewetting events may emit up to 13.7 g CO₂ m⁻² day⁻¹ (Datry et al., 2018b, Box 1) and 21.1 g CO₂ m⁻² day⁻¹ (Gallo et al., 2014), respectively. Annual contributions of IRES to global CO₂ emissions may therefore be much greater and more important than those of perennial rivers, magnified by the spatial abundance and ubiquity of IRES across the Earth's surface.

Biodiversity in Intermittent Rivers and Ephemeral Streams

From Microbes to Elephants, IRES Support High Biodiversity

Microbiota, including bacteria, archaea, protozoa, fungi, cyanobacteria, and algae grow both in benthic habitats as well as in the water column itself and comprise the base of aquatic foodwebs (Pusch et al., 1998; Weitere and Arndt, 2003; Battin et al., 2016). Flow intermittence can cause differences between environmental conditions in IRES and perennial rivers, such as water temperature, dissolved oxygen, dissolved organic matter, inorganic nutrients, flow velocity, and light. These differences in environmental conditions likely drive differences in the composition of microbiota between IRES and perennial biomes (Romaní et al., 2017). Microbes are known to play a key role in biogeochemical processes in rivers, such as organic matter decomposition, and our understanding of microbial biodiversity continues to advance as molecular approaches make it easier and more affordable to quantify microbial diversity. For example, pyrosequencing uncovered compositional differences in bacterial communities on cobbles during flowing, non-flowing, and rewetting stages of flow intermittence in a Mediterranean IRES (Timoner et al., 2014).

Plant communities that inhabit IRES are influenced by the dynamic hydrologic conditions which create favorable environmental conditions for both vascular aquatic and riparian plants (Sand-Jensen and Frost-Christensen, 1998; De Wilde et al., 2014). Plants comprised of various functional groups, including emergent and submerged, respond differently to flow intermittence (Brock and Casanova, 1997). Some emergent helophytes, such as Cyperaceae and Juncaceae, can tolerate complete drying of above and below-ground biomass. Submerged plants usually die during drying conditions except for desiccation-resistant seeds that can germinate upon rewetting (Brock et al., 2003). Thus, the availability of "seed banks" is an important attribute of plant communities allowing persistence in IRES.

Aquatic and terrestrial invertebrates are arguably the most well-studied organisms inhabiting IRES (Leigh and Datry, 2016). The dynamic environmental conditions and habitat types found within IRES influence the composition, abundance, and diversity of invertebrates (Datry et al., 2016a), often driving differences in community composition and richness between IRES and perennial rivers. In general, taxonomic richness of aquatic invertebrates in IRES is lower than that of equivalent-sized perennial rivers (Datry et al., 2014a; Soria et al., 2017). However, when the terrestrial phase of IRES is considered, total invertebrate richness, accounting for aquatic and terrestrial taxa, may be similar or even higher in IRES. Typically, community composition of invertebrates changes along a gradient of flow intermittence, with IRES communities being subsets of the species found within sites with more permanent flow (Datry et al., 2014a). IRES invertebrate community composition shifts in response to timing, duration, and frequency of lotic phases, often with distinct invertebrate communities within each hydrologic phase. For example, mayflies, stoneflies and caddisflies can typify aquatic invertebrate communities during the flowing phase, whereas odonates (dragonflies and damselflies), aquatic beetles, and true bugs may dominate during the lentic phase (Bonada et al., 2007). During the terrestrial phase, both terrestrial and semiaquatic invertebrates colonize IRES, including insects (mainly ground beetles), arachnids, centipedes, crustaceans, millipedes, snails, springtails, and worms (Steward et al., 2017).

Fishes inhabit intermittent rivers, including those in arid regions of Africa and Australia (Lévêque, 1997; Allen et al., 2002). Generally, fish diversity is lower in IRES compared to equivalent-sized perennial systems because relatively few species can cope with flow intermittence. However, some fish are adapted to breathing oxygen from the atmosphere (e.g., African sharptooth catfish [*Clarias gariepinus*]). Persistence of most fishes within IRES is facilitated more by movements into and out of drying habitats than by their ability to resist desiccation, although pools can be an important refuge for stream fishes (Magoulick and Kobza, 2003).

Box 1 The 1000 intermittent river network: measuring the importance of IRES to global carbon and CO₂ emission. The “1000 Intermittent River Project”: Measuring the Importance of IRES to Global Carbon and CO₂ Emissions

Drastic changes in flow regime and IRES distribution prompt fundamental questions: how are the biogeochemistry and biodiversity of river networks affected by these changes? How do these alterations vary across climatic and biogeographic regions?

To address these questions, an international group of researchers started a multidisciplinary effort called the “1000 Intermittent Rivers Project” (#1000IRP on Twitter). The project’s main goal is to merge individual knowledge, forces, and passions through simple, consistent, and comparable joint experiments in IRES worldwide.

Since its 2016 inception, the project has grown to over 120 participants from 28 countries (Datry et al., 2016b). Although some regions, including Africa and Asia, remain poorly represented in this collaborative effort, the group continues to recruit new participants for future experiments.

The first coordinated experiment done by #1000IRP is recognized for contributing to the understanding of global C cycle and CO₂ emissions (Datry et al., 2018b; Shumilova et al., 2019). In this global experiment, researchers collected leaf litter and other organic matter and sediments from 212 dry riverbeds across the globe. Samples were then sent to a single laboratory for further processing.

One major finding from this experiment was that rewetting events in IRES contribute up to 10% of daily CO₂ emissions from all rivers and streams. During rewetting, dissolved organic carbon, phenolics, and nitrate are leached from sediments and organic matter are washed downstream. This indicates that rewetting phases in IRES are “hot moments” of biogeochemical activities that likely play an important role in how rivers function.

As more rivers begin to dry as a result of climate change and increased water demands, there will be a continued need to study IRES at the global scale through collaborative experiments.

Swimming allows fish to disperse to access food and habitat resources within IRES during their lotic hydrological phases (Kingsford et al., 2006; Wardle et al., 2013). IRES provide an important habitat type for some fish species during their life cycle. For example, IRES constitute a key spawning and juvenile rearing habitat for the federally endangered coho salmon (*Oncorhynchus kisutch*) along the US Pacific Coast (Wigington et al., 2006). IRES likely provide abundant food resources through terrestrial subsidies and fish may experience lower levels of competition and predation compared to perennial rivers (Courtwright and May, 2013; Kerezszy et al., 2013).

Other wildlife, such as amphibians, reptiles, birds, and mammals use IRES for a variety of reasons, especially in arid and semiarid regions where water is limited. Most amphibians are well-suited to inhabit IRES because of their life cycles which constitute both aquatic and terrestrial stages (Wells, 2010). Many reptiles are attracted to IRES because of higher humidity compared to terrestrial habitats. Bird species that are not dependent on water often congregate in riparian areas of IRES to roost and reproduce (Shine and

Brown, 2008). Mammals ranging in size from rodents (Gibson and Olden, 2014) to elephants (Elephantidae) and hippopotamuses (*Hippopotamus amphibius*) (Kok and Nel, 1996; Lakshminarayanan et al., 2016) are also commonly found in and around IRES (Kerezesy et al., 2013). Although IRES likely attract wildlife during lotic and lentic hydrologic phases, dry riverbeds are movement corridors for all types of terrestrial vertebrates including lizards, birds, rodents, lagomorphs, carnivores, and ungulates (Sánchez-Montoya et al., 2016).

Strategies for Persistence in IRES

To persist in the dynamic conditions of IRES systems, organisms have a variety of adaptations that are often categorized into traits of either resistance or resilience to flow intermittence (Bonada et al., 2007; Robertson and Wood, 2010; Robson et al., 2011; Datry et al., 2014a). Traits are broadly characterized into physiological, morphological and life-history features of organisms. Resistance can be defined as the capacity of a species, a community, or an ecosystem to persist unchanged by and during a disturbance (Stanley et al., 1994; Vander Vorste, 2015) and includes diapause, desiccation-resistant eggs, cocoons or cells, body armoring and aerial respiration (Bonada et al., 2007; Robson et al., 2011). Resilience, or the capacity to recover from disturbance, is favored by traits such as short lifespans with early maturity, asexual reproduction, and strong aerial or aquatic dispersal ability (Bonada et al., 2007; Datry et al., 2014a; Vander Vorste, 2015). Typically, there are several sources of colonization of IRES by taxa with either resistant or resilient strategies (Fig. 3).

Organization of Metacommunities Within IRES

A metacommunity is a set of local communities connected by dispersal (Leibold et al., 2004). In a metacommunity, community assembly is determined by the capacity of species to tolerate and develop under local environmental conditions (environmental sorting) and to reach the community through dispersal (i.e., spatial connectivity and organism dispersal ability). IRES support dynamic metacommunities in which local communities experience alternating aquatic and dry phases as well as changes in

Biotic community resistance and resilience to river drying

Resistance strategies

allow organisms to survive flow cessation and persist within a stream reach

Sources of resistance in IRES

Remnant pools

As stream riffles dry, organisms can survive in remnant pools if environmental conditions remain favorable

Hyporheic zones

Once surface water is lost, some organisms can survive in saturated hyporheic zones (saturated interstitial sediments below and adjacent to the streambed).

Desiccation-resistant stages

Eggs, larvae, pupae or adult life stages that can resist desiccation for up to many years before becoming active again upon stream rewetting.

Resilience strategies

allow organisms to recolonize a previously dry stream reach from elsewhere

Sources of resilience in IRES

Dispersal by drift

Organisms entrained in water flowing downstream or on floating detritus

Crawling and swimming

Crawling and swimming upstream or downstream

Aerial dispersal

Aerial adult life stages of aquatic insects

Fig. 3 Examples of traits that enhance the resistance and resilience of aquatic invertebrates to surface water drying Adapted from Vander Vorste, R. (2015). The hyporheic zone as a primary source of invertebrate community resilience in intermittent alluvial rivers: Evidence from field and mesocosm experiments. PhD Thesis. University of Lyon 1: Lyon, France. 210 pp.

hydrological connectivity, forming a mosaic of habitats that usually connect and disconnect each year (Datry et al., 2016a). These spatiotemporal dynamics leads to recurrent changes in community assembly mechanisms (Datry et al., 2016a; Sarremejane et al., 2017).

Environmental sorting is the main driver of aquatic organism assembly during flow recession phases because drying creates a strong filter eliminating the least adapted species. On the other hand, dispersal processes should be more important when flow resumes as organisms recolonise from surrounding habitats (Datry et al., 2016a, Sarremejane et al., 2017). However, the interplay of these mechanisms is likely to differ for species adapted to lotic, lentic, and terrestrial habitats, for example, dispersal-related processes likely being more important for lotic and terrestrial species as flow recedes. More research is needed to determine which local conditions (e.g., drying frequency, flow state and water chemistry) and connectivity features (e.g., distance to perennial reaches and isolation within the river network) drive community assembly where and when in the river metacommunity. Understanding this will allow better characterization of community assembly in response to flow intermittence.

Management of Intermittent Rivers and Ephemeral Streams

Ecosystem Services Provided by IRES

IRES provide important cultural, regulating, and provisioning ecosystem services, varying between aquatic and dry phases (Datry et al., 2018a; Koundouri et al., 2017). IRES bring spiritual and inspirational enrichment and are also widely appreciated for recreational opportunities and aesthetic values. Regulating ecosystem services provided by IRES include flood protection and water purification. As discussed previously, IRES support an important role in riverine nutrient cycling and contribute to global CO₂ emissions. Provisioning ecosystem services provided by many IRES include fresh water and food. The dynamic flow regime of IRES also influences provision and types of these various ecosystem services. For example, IRES can support recreational fishing during wet phases but be used as a path by walkers or as foraging areas for livestock during dry phases.

Protection and Management of IRES

Relatively little attention has been given to IRES protection and management, perhaps because dry channels have, until recently, been perceived as lifeless symbols of human impacts or poorly functioning river systems. In many countries, IRES are not legally recognized as part of the river network (Acuña et al., 2014), and although their recognition has increased in the past decade, their status as waterways that are worth protecting is still debated by authorities in the United States (Marshall et al., 2018, Box 2). In Europe, IRES protection status depends on how “waterbodies” are classified by regional authorities or each river basin, with differences in the ways that IRES are perceived and protected across countries (Fritz et al., 2017). In Australia where IRES are prevalent, they are included in most management plans and legislation. Nevertheless, IRES are sometimes included within protected areas and, when this is so, their conservation focuses on maintaining their natural flow regime and the connectivity to aquatic refuges (e.g., pools, Leigh et al., 2015). Ephemeral streams, i.e., those dry most of the time, are typically prone to being dismissed from management plans, and limited knowledge about their ecosystem services often hinders their conservation (Boulton, 2014).

IRES are often omitted from ecological monitoring programs implemented to characterize the ecological quality of rivers. Most biomonitoring techniques have been developed for perennial rivers and often perform poorly in IRES, particularly because reference communities (i.e., under those experiencing little or no human impact) usually have fewer taxa than those in their perennial counterparts (Stubbington et al., 2018a). Typically, biomonitoring index scores decrease with flow intermittence as well as with human impacts (Wilding et al., 2018). Biomonitoring tools therefore need modification to account for the natural variability of IRES communities and to efficiently disentangle the effect of flow intermittence from human impacts (Stubbington et al., 2018a). However, characterization of communities across the range of aquatic and terrestrial conditions that occur in IRES—including responses to natural hydrological variability and to human stressors is still needed. Such research will enable the development of effective biomonitoring strategies, which include terrestrial and lentic phases, therefore recognizing the dynamism of these ecosystems (Stubbington et al., 2018b).

Future of IRES and Global Change

In IRES, flow cessation and drying can have natural and non-natural causes. Disentangling these causes is rarely easy (Gallart et al., 2017), and often, multiple causes interact. Different processes generate natural drying in IRES: transmission losses (e.g., infiltration of surface water into porous streambeds), evapotranspiration, downward shifts in groundwater tables, hillslope runoff recession, and freeze-up (Larned et al., 2010). Anthropogenic drying can be due to one or more of the following human activities: alteration of land-use patterns, flow regulation, surface or groundwater extraction, and reduced precipitation and increased evaporation resulting from climate change (Palmer et al., 2008; Steward et al., 2012).

The flow regimes of streams and rivers are prone to severe alterations worldwide, mainly in response to drying climates across much of the globe coupled with rapidly increasing human demands. Consequently, the occurrence and spatial and temporal extent of IRES are both increasing over time (Larned et al., 2010; Datry et al., 2018a). Shifts from perennial to intermittent flow regimes are projected by the 2050s for streams and rivers across much of the globe, including north-eastern and south-western Australia, Brazil, California, the Caribbean, southern Africa, West Africa and around the Mediterranean Basin (Döll and Schmied, 2012). Conversely,

Box 2 Case study of current environmental protection of IRES systems in the United States. Does Environmental Policy Protect Intermittent and Ephemeral Streams?

Case Study: Waters of the United States (WOTUS)

In the United States, the Clean Water Act (CWA) provides legal protection of the ecological health of rivers. However, a debate over whether intermittent and ephemeral streams should be included in these protections was sparked in 2006 in the U.S. Supreme Court. Guidance by the Supreme Court decision stated that rivers with permanent or seasonal hydrologic connections to Traditionally Navigable Waters should be protected. Without a relatively permanent hydrologic connection, streams with a connection through hydrological and ecological factors that affect the chemical, physical, and biological health of navigable waters should also be protected.

Following the Supreme Court decision, inclusion of intermittent and ephemeral streams in the CWA by the US Environmental Protection Agency (USEPA) has wavered. Freshwater scientists have been in favor of including intermittent streams within the jurisdiction of waters of the United States, in part, due to the recognition that these streams provide “many ecosystem services, including water provision and purification, that contribute substantially to securing water quantity and quality” as stated in [Marshall et al. \(2018\)](#). Following an independent review of > 1200 scientific publications, USEPA's Science Advisory Board informed a Clean Water Rule in 2015 aiming to recodify the waters of the United States to include intermittent streams. As of 2019, the US federal government has failed to implement the Clean Water Rule despite direct advice from freshwater scientists ([Acuña et al., 2014](#); [Marshall et al., 2018](#); [Sullivan et al., 2019](#)). Without adequate protection, the US puts 58% of all waterways in the contiguous US at risk of degradation ([Marshall et al., 2018](#)).

some natural IRES are predicted to become perennial in Siberia and parts of Canada and Alaska due to warmer winters ([Döll and Schmied, 2012](#)). Similarly, many natural IRES are becoming more intermittent and dry periods are getting longer ([Larned et al., 2011](#)). However, trends of increasing drying are not universal and controlled releases from dams and weirs, discharge of agricultural, industrial and urban effluents, inter-basin transfers and snow melt can contribute to decreased intermittence of many IRES, turning some of them artificially perennial ([Hassan and Egozi, 2001](#); [Steward et al., 2012](#)). In some water-scarce areas, the baseflow of urban rivers is maintained by wastewater effluents ([Luthy et al., 2015](#)). Reversal of seasonal patterns of drying are observed in other areas, where channels are used to carry irrigation flows released from upstream dams: peak flows from dam releases occur when flows in the channel used to cease whereas dams retain water, sometimes causing flow to cease at a time when the downstream river historically flowed ([Barnett and Pierce, 2009](#)).

Summary

Intermittent rivers and ephemeral streams contribute substantially to global biogeochemical processes and help sustain biodiversity. In many regions of the world, this biome dominates as the main freshwater ecosystem type compared to their perennially flowing counterparts. A dynamic flow regime is what sets IRES apart from other aquatic ecosystems; creating opportunities for lotic, lentic, and terrestrial organisms. Many of these organisms have specific trait adaptations that allow them to persist through phases of flowing water, pooling, and completely dry channels. Across the landscape, biotic communities can change quickly from phase to phase because they are connected by dispersal forming metacommunities. IRES likely play a major role in how metacommunities

are organized because of their dynamic nature. Although IRES are becoming more widely recognized for their importance in providing ecosystem services, they are increasingly under threat by global change. Under future climate change, many more perennial rivers are expected to become intermittent or ephemeral and drying may become more severe. Protection of this biome, which is currently limited compared to perennial rivers, continues to be an issue to be resolved.

Abstract

Riparian areas are the terrestrial interface between freshwater and upland environments, encompassing important ecotones where aquatic and terrestrial biophysical processes intersect to create unique and dynamic habitats. Diverse riparian habitats support organisms adapted to variable hydrologic conditions associated with seasonal precipitation patterns and cycles of erosion and deposition. Riparian ecosystems encompass habitats for both aquatic and terrestrial species, making these areas biodiversity hotspots across river networks. Riparian restoration is an effective conservation practice that can benefit terrestrial and aquatic organisms as well as promote water quality. Owing to their high conservation value, the protection and restoration of riparian areas has become a primary objective of land-management interests globally. Restoration practices include adjusting or targeting land- and water- management activities to meet conservation goals. Effective riparian restoration strategies will vary across biomes in response to distinct biophysical and social considerations at stream corridor, catchment, and regional scales.

Characteristics of Riparian Habitats

Riparian areas are semiterrestrial systems extending from water's edge to the uplands, their spatial extent controlled by surface and groundwater hydrology (Naiman et al., 2005). Riparian areas include floodplain and streambank landforms which exhibit unique soil and vegetation characteristics resulting from periodic inundation. Across biomes, riparian areas and the biogeochemical systems they represent vary based on climate, lithology, and elevation, as well as land use, cultural, and political contexts. Riparian habitats extend from mountain headwaters to coastal lowland streams and thus encompass a wide variety of habitats and vegetative communities.

The structure, function, and maintenance of riparian habitat derive from both lateral and longitudinal processes. Riparian areas are gradients where transitions and exchanges occur between freshwater and upland ecosystems. They also function as corridors where organisms and materials flow in linear paths along streambanks. Hydrological, biological, and geochemical processes affect the lateral and longitudinal characteristics of riparian systems. Numerous feedbacks connect riparian systems to both upland and freshwater ecosystems. Processes that influence riparian systems include deposition and erosion of streambanks (sediment transport), variations in the timing and magnitude of streamflow, and nutrient transfers from stream to streambank and back. Freshwater flows can control local habitat, leading to riparian communities uniquely cued to predictable seasonal patterns of discharge. Terrestrial and aquatic disturbance events affect the flow of materials both across the riparian gradient from freshwater to upland, as well as along riparian corridors from drainage divide to sea. Long-distance seed dispersal is facilitated by streamflows and flood events and creates natural riparian vegetation patterns across hydrologically connected river networks (Bourgeois et al., 2016).

Ecosystem Services Provided by Riparian Systems

Riparian areas provide a suite of valuable ecosystem services that make them a focus of conservation efforts around the world (Dufour et al., 2011; Bagstad et al., 2013; Penaluna et al., 2017, 2018). Intact riparian vegetation and hydro-geomorphic processes directly affect streamflow and water temperature, instream habitat complexity, water quality, and biodiversity that contribute to economic values. These regions also provide significant social and cultural value to human communities around the world.

Streamflow and Water Temperature: Streamside vegetation increases water infiltration rates, potentially mediating high flows associated with precipitation patterns, and enhancing groundwater recharge that supports baseflow conditions during dry periods (Caissie, 2006). Riparian areas can also store cool water from spring flood events, releasing stored waters into stream channels through subsurface flows during the summer season, effectively increasing baseflow volumes and regulating stream temperatures (Elmore et al., 2003). Shading of stream channels by intact riparian forests and vegetation regulates stream temperature, which in turn supports aquatic ecosystems and cold-water dependent fishes (Beschta et al., 1987). Vegetation can contribute to cool thermal regimes in off-channel habitats (i.e., alcoves, side channels) by enhanced subsurface flow from floodplain springbrooks and lateral seeps (Poole and Berman, 2001; Ebersole et al., 2003). Riparian areas also help maintain streamside thermal microclimates by altering wind speed, humidity, and local air temperature (Olson et al., 2007).

Instream Habitat Complexity: Woody vegetation in riparian areas is an important source of large wood recruitment to streams. Instream large wood reroutes water to transform stream-channel morphology, creating complex instream habitat important for native aquatic species (Bilby and Bisson, 1998). The root structures of streamside vegetation stabilize streambanks, minimize erosion, and benefit stream habitat quality.

Water Quality: Intact riparian vegetation enhances water quality by protecting streams from detrimental effects of upslope land uses by absorbing flood flows, increasing evapotranspiration, and limiting downstream sedimentation (Naiman et al., 2005). Riparian vegetation filters nutrients from agricultural chemical treatments or urbanized areas as runoff drains into stream channels during storm events (Vidon et al., 2010). Sediments, nutrients, and toxic materials are filtered from floodwaters or runoff by particulate trapping and the binding of materials to leaf litter and soils in these areas (Correll, 1999). For example, concentrations of nitrate in shallow groundwater decline as the groundwater moves through riparian zones before reaching stream channels (Davis et al., 2007).

Biodiversity: Riparian habitats can support a large proportion of a region's biodiversity, including numerous riparian-obligate organisms (Naiman and Decamps, 1997; Sabo et al., 2005; Olson et al., 2007). Other species use riparian habitats to complete their life cycle, particularly migrating birds, butterflies, and mammals. Networks of riparian areas along stream channels provide important habitat and dispersal corridors. Further, because riparian areas provide cool, moist microclimates, they may be particularly important for conservation prioritization as climates change in the future (Seavy et al., 2009; Beier, 2012; Capon et al., 2013; Krosby et al., 2018).

Cultural and Social Value: In addition to their services supporting ecosystems and water quality, riparian areas are also culturally and socially important. The value of riparian systems can be seen across rural and urban societies around the world. Along the Oueme and Okpara Rivers of Central Benin, West Africa, riparian forests are an integral element of *ibu odo*, or sacred pools of cultural importance (Ceperly et al., 2010). Riparian systems are additionally valued for their function as windbreaks and hunting grounds, supporting hunting and fishing activities of cultural and economic importance. In a study along a river in Indonesia, Vollmer et al. (2015) found that riparian corridors provide high value non- or indirect-use cultural services to low-income urban residents. Riparian areas can function as greenspaces and parks, providing sources of recreation and tourism and thus having passive economic value (Johnson and Carothers, 1982). Private property also benefit economically from riparian vegetation, as studies have shown a positive relationship between property values and distance to riparian areas in the USA (Qui et al., 2006; Bin et al., 2009).

Degradation of Riparian Habitats

Owing to their location next to vital waterways, riparian ecosystems are subject to severe degradation by human land and water usage (Fig. 1). The many detrimental impacts on riparian habitat, stream habitat, and water quality are well documented in the literature (Mensing et al., 1998; Feld et al., 2011). Forestry, agriculture, urbanization, and other human land uses have reduced or eliminated riparian areas around the world. Deforestation is a significant driver of riparian habitat degradation. Swift (1984) found that riparian area has been reduced by more than 66% by development, with more than an 80% reduction in riparian vegetation in arid areas of the western and midwestern USA. In Europe, floodplain forests have shrunk by an estimated 88% as a result of land-clearing (UNEP-World Conservation Monitoring Centre, 2000). Common alterations to riparian systems include simplification of stream channels and floodplain drainage to support infrastructure development. Stream channelization can result in floodplains being entirely cut-off from river channels, reducing the area of slow-water habitats and wetlands vital to both biotic and hydrological functions. Existing riparian systems are further compromised by pollution (both point- and non-point source), timber harvest and extraction, invasive species, and erosion from agricultural practices and roads (Naiman and Turner, 2000).

Just as land-management actions can greatly reduce or destroy riparian habitat, water management decisions involving water diversion, impoundment, or withdrawal can alter hydrologic processes, reduce inundation of riparian floodplains, and change riparian ecosystems. Floodplain regions can be intensely simplified for flood control purposes, and water withdrawals for agricultural uses can result in floodplain regions being cut-off entirely from river channels. Altered hydrologic regimes can reduce or eliminate riparian habitats throughout the river network. Vegetation patterns can be significantly affected as upland species encroach into riparian areas, causing shifts in vegetation community structure and function.

Fig. 1 Anthropogenic alterations to riparian ecosystems across a watershed may be due to changes in natural disturbance processes, draining and in-filling of floodplains for development and road construction, agriculture, timber harvest, or urbanization. All of these changes result in modifications to the functional processes embedded in riparian systems that support productive aquatic-terrestrial ecosystems. Kathryn Ronnenberg, US Forest Service, Pacific Northwest Research Station.

Restoration Policies and Practices: Tools in the Toolbox

Riparian restoration policies and practices aim to recover degraded or destroyed riparian systems. These efforts focus on land- and water-management activities that can help restore or improve riparian condition based on target criteria. Restoration efforts can include land-management decisions, protective policy measures to govern riparian corridors, and timing of water releases to more closely match natural flow regimes, along with on-the-ground actions directed at physically restoring riparian biota, structure, and function.

Land Management

Restoration of degraded riparian habitat can be implemented at site scales (for individual projects) or across broader extents encompassing multiple land uses or ownerships. Site-scale projects can include active restoration actions intended to improve site condition (e.g., tree-planting or seeding, vegetation thinning, channel grading, invasive species removal). Relinking disconnected floodplains to their river, particularly where channels have downcut or have been simplified, may include grading or excavation to restore sinuosity, restructure channels, and sculpt topographic conditions capable of supporting riparian vegetation (Manci, 1989). For example, active restoration measures including channel widening and sediment addition have been used to restore a section of the Tama River near Tokyo from a single-thread incised channel into a braided gravel-bed river (Nakamura et al., 2006).

Other restoration actions rely on passive actions intended to reduce environmental stress. Passive restoration relies on natural processes to guide the recovery process. These efforts can be site-specific, reducing factors or causes of degradation at specific site. A common example in the USA is the use of riparian fencing to exclude cattle grazing (Fig. 2). Excluding cattle grazing from riparian areas can result in an increase in riparian vegetation, greater streambank stability, and shifts in stream channel profile from wide and shallow to narrow and deepened channels.

At larger spatial extents, one way to protect or improve riparian systems is through policy that prescribes or recommends limitations in actions that can adversely affect riparian systems or have detrimental impacts on stream water quality. To meet water quality and aquatic habitat goals, policy-prescribed standards generally establish a target condition for riparian areas and limit land uses in order to promote riparian vegetation. Worldwide, riparian-management policies enacted by local, regional or national governments vary considerably based on land use and ownership and by whether they are voluntary or mandated policies (Cashore and McDermott, 2004; Lee et al., 2004). One common strategy is the adoption of fixed-width stream-adjacent buffers where certain

Fig. 2 Response in riparian condition following passive restoration actions in Spawn Creek near Logan, Utah, USA. Prior to restoration, the riparian area was frequently grazed by cattle, resulting in reduced riparian vegetation and alterations to stream banks. Livestock exclusions were set up at the site in 2006. Vegetation response is clearly seen in the post-restoration photo from 2015 (A1) compared with conditions in 2004 prior to restoration action (A2). Within the restoration period, an increase in riparian vegetation is observed in 2015 (B1) compared with photos from 2 years earlier (B2). The increase in vegetation has stabilized stream banks and reduced erosion. Photographs provided by PACFISH/INFISH Biological Opinion Effectiveness Monitoring Program (United States Forest Service, Fish and Aquatic Ecology Unit, Logan, Utah).

management actions are prohibited (Richardson et al., 2012). For example, the Ibrahim River in Lebanon is protected by 500 m buffers due to the rivers historical and cultural significance (Makhzoumi and Abboud, 2005).

Voluntary restoration or conservation actions often include incentive-based programs for landowners to maintain or restore riparian vegetation. These approaches are particularly necessary in landownerships where policy protection may be minimal or absent, and where land uses are focused on economic gain and resource extraction. Technical assistance from agencies and institutions, such as the Soil & Water Conservation Districts in the USA, can provide important capacity to individual landowners seeking to adopt innovative riparian-management practices. These programs can be crucial for targeting riparian restoration in areas where restoration action may be most effective, for example restoring riparian areas in agricultural regions to remove nonpoint source pollutants from surface waters.

Water Management

Characteristics of annual discharge, including the timing, magnitude, and frequency of peak flows, are crucial to maintaining and connecting riparian habitat (Poff et al., 1997). Simplification and alteration of flow regimes contribute to riparian ecosystem degradation. Streamflow restoration, implemented through water-management policies and practices, can improve riparian condition and function. Tools for restoring streamflow include changing the timing and quantity of water releases to mimic natural inundation patterns and the reallocation of water rights from extractive uses to instream purposes.

González et al. (2015) reviewed riparian restoration projects from around the world and found that hydro-geomorphic approaches (e.g. dam operations, controlled floods) were the most frequently adopted riparian restoration practice based on their review. Flood pulsing is a significant driver of riparian function (Junk et al., 1989; Tockner et al., 2000). High flow or flood events

that are a characteristic of the natural flow regime (Poff et al., 1997) allow for seed dispersal of riparian plants, the creation of complex stream bars and channels, and the maintenance of dynamic riparian systems. Water flows may be managed to allow for natural pulses or high-flow events that aid in riparian vegetation development (Rood et al., 2005; Merritt et al., 2010).

Scientists and engineers have collaborated to investigate and model the effects of dam removal or adjustments to water-release schedules on sediment transport and riparian structure and function. In the Colorado River basin of Mexico and USA, experiments have been conducted to examine effects of high flows on sand bar development and riparian seed dispersal (Ralston, 2010; Melis et al., 2015). In the northeastern United States, The Nature Conservancy has partnered with the Army Corps of Engineers to better understand linkages between surface elevation and riparian vegetation to better manage flows for environmental purposes (Marks et al., 2014). However, many challenges remain to restore hydrologic connectivity to maintain processes important to riparian ecosystems at watershed-scales.

Developing environmental flow thresholds (often called “e flows”) to meet multiple ecosystem needs is an increasing priority for water managers. In many societies, water has traditionally been allocated for human uses such as industry, irrigation, and municipal uses before considering ecosystem water needs. Water may be diverted from streams, reducing streamflow volumes or even drying the stream entirely, reducing or destroying available riparian habitats. To alleviate this problem, environmental flow transactions, agreements under which water-right holders commit to a reduction in water use to serve environmental purposes (Aylward, 2013), have become a major focus of restoration efforts around the world. For example, in the Columbia River Basin of the Canada and USA, the Columbia Basin Water Transaction Program transfers water rights to instream purposes to support functioning riparian and riverine ecosystems across the 674,000 km² watershed. Over a 14-year period, the program has supported projects that restore flows to over 2414 km of streams within the Columbia River Basin, protecting over 12 million megaliters of water over the next 100 years (McCoy et al., 2018).

In arid regions, where water resources are scarce, innovative approaches showcase the benefits of allocating limited water supplies to promote streamside vegetation. One example is the short-term water use agreements developed by the Arizona Land and Water Trust in Arizona, USA, under which water users agree not to pump groundwater or divert surface waters over a pre-determined period of time in order to meet short-term ecological goals or test the efficacy of certain restoration actions. Water use agreements offer a flexible tool that allows for innovations and partnerships in landscapes where economic and conservation goals need to be carefully balanced. This pragmatic approach to restoring riparian corridors acknowledges that in some places, it may not be feasible for entire landscapes to be managed as biodiversity reserves (Citron, 2010).

The Managed Aquifer Recharge site (MAR5) of the Gila River Indian Community is another example of an environmental water transaction that seeks to balance multiple needs and provide ecological, social, and cultural benefits. Colorado River water is delivered to central Arizona through the Central Arizona Project aqueduct, which spans 336 miles and requires pumping water up-gradient. The MAR5 restoration project directs a portion of the Gila River Indian tribe’s water right toward groundwater recharge. This allows farmers of the Gila River Indian Community to access less expensive groundwater, provides community members the ability to visit a flowing stretch of river, and returns riparian vegetation to a previously dewatered river section (GRIC, 2015). The community vision of promoting multiple goals is an example of the many innovations in managing water to support riparian systems around the world.

Riparian Restoration Strategies

The numerous tools available for both land and water management require a clear strategy to articulate project goals and guide the planning, coordination, implementation, and monitoring of riparian restoration actions. The spatial and temporal scope of riparian restoration can be a significant driver of the restoration strategy. For example, restoration of small stream reaches may promote a direct approach (e.g., tree planting, terrace grading, or large-wood placement). These projects often have very specific goals focused on the stream reach, for example local habitat restoration, or enhancing stream-side shade or filtration of diffuse pollutants from an adjacent land use, and involve a short timeline for planning and implementation. A large-scale, long-term restoration strategy may coordinate a variety of targeted riparian restoration practices at a watershed or corridor scale to promote multiple conservation objectives. A process-based strategy can focus on restoring riparian functions that create and form diverse habitat conditions across an entire river system. Emerging strategies for riparian restoration have focused on scaling up restoration efforts, coordinating management actions, proactively planning restoration under climate change, and developing new tools and sampling designs to monitor restoration efficacy and before- and after- effects.

Scaling Up Restoration Efforts

Riparian areas provide important ecosystem services from headwater to estuary. Over time, as tools and approaches to riparian restoration have developed, the focus of work has begun to shift from reach-scale projects affecting local riparian habitat to strategies designed to restore or improve riparian function at the scale of the river-basin (Stella et al., 2013). Lorenz and Feld (2013) found that degraded riparian areas upstream can effectively neutralize the benefits of site-scale restoration downstream. Rather than opportunistically pursuing riparian restoration practices on a case-by-case basis, targeted approaches to riparian restoration consider restoration actions in the context of broader watershed processes (Boudell et al., 2015). There is an increasing focus on restoration strategies to maintain ecological functions within the context of natural disturbance regimes (Poff et al., 1997; Reeves et al., 1995).

Such a management approach is intended to support species of concern and their habitat by maintaining key ecological linkages, while balancing human consumption, cultural, and recreation needs.

Watershed-scale restoration planning is complicated by landownership and jurisdictional oversight, as well as the complex network structure of river systems. Watersheds encompass multiple jurisdictions, and thus large-scale riparian restoration requires coordination across institutions and individuals with diverse land- and water-management goals that operate under different standards depending on ownership and land use. The management of riparian areas is particularly complicated as these areas encompass private property rights associated with land use as well as public interests in the protection of waterways (Boisjolie et al., 2017). This results in a wide range of variability in protective standards which fragments riparian management at the watershed scale, creates gaps in protective efforts along the river corridor, and results in complex patchworks of protective measures within and across watersheds (Boisjolie et al., 2019).

Integrated Watershed Management

Considerable coordination is necessary to develop restoration strategies at the watershed scale. Integrated watershed management is emerging as a means for coordinating planning to effectively implement riparian restoration from a multi-ownership perspective. Ideally, integrated watershed management provides a holistic framework to understand the biophysical and social landscape of the river and its valley: evaluating the basin hydrology, understanding land and water uses, engaging local communities, and applying appropriate science to guide the adoption of protective and restorative measures. The approach is simultaneously research-driven and applied, considering both economic and ecological sustainability when developing land-use goals (Naiman et al., 2005). It has been adopted by managing entities and collaborative efforts around the globe, with multiple examples of approaches based on regional considerations (Flitcroft et al., 2018). Steps involved in an integrated watershed plan may include social and technical actions. Developing partnerships with key stakeholders, facilitating the involvement and input of these stakeholders, and implementing educational outreach are all steps to developing a successful management plan. Technical approaches may include the gathering of data to characterize the watershed, the creation of monitoring plans, the identification of issues and risks, and the development and implementation of catchment management plans (Ireland Environmental Protection Agency, n.d.).

An integrated watershed-management approach for riparian restoration encompasses riparian zones throughout the river network. As outlined by González et al. (2017), integrated conservation of riparian zones is most effective when clear restoration goals are developed that can be properly evaluated. Goals and planning should encompass multiple spatial and temporal scales. Conserving riparian regions across a watershed scale also necessitates pursuing numerous approaches to restoration and protection, including technical, socio-economic, and legal avenues.

Effective riparian restoration is difficult owing to the multi-disciplinary knowledge necessary to plan, implement, and monitor practices. Depending on the location, a restoration strategy may require expertise in forest management, land-use policy, restoration ecology, geomorphology, aquatic ecology, fisheries, and hydrology (Dufour et al., 2018), as well as input from sources of local and cultural knowledge (Flitcroft et al., 2018). A key factor for the efficacy of integrated watershed management is the development of a basin-wide knowledge network allowing for collaboration. Coordination across watersheds and landownerships supports knowledge networks or social infrastructure that incorporates diverse perspectives to aid in effective planning, implementation, and monitoring (Flitcroft et al., 2009). In many parts of the USA, watershed councils provide for coordination of riparian restoration activities through collaborative processes. New technical tools such as Lidar or satellite imagery also enhance and enable large-scale modeling that can aid in holistic planning and large-scale management. Just as restoration design and planning is attempting to “scale-up”, so are efforts to educate, communicate, and collaborate on science and management elements central to large-scale restoration.

Pro-Active Restoration Planning Under Climate Change

Riparian areas are a special conservation focus under a changing climate because of their importance in supporting biodiversity. Perry et al. (2015) describes the multiple potential effects of climate change on riparian ecosystems, including both direct effects on wildlife and vegetation, and indirect effects on streamflow, temperature, and precipitation. To respond to anticipated changes in conditions across watersheds, more attention is being paid to pro-active restoration planning and design that considers potential climate-change effects (Flitcroft and Giannico, 2013; Perry et al., 2015; Tonkin et al., 2019). More forecasting tools may be needed to effectively plan for alternative futures and adaptively manage river corridors under a changing climate (Tonkin et al., 2019). Advances in geospatial data have led to the emergence of tools to identify priority riparian areas for climate adaptation that can help better target restoration actions (Krosby et al., 2018).

Effectiveness Monitoring

As riparian restoration strategies expand to consider watershed-scale processes and target natural ecological processes, monitoring long-term restoration effects becomes increasingly important. Monitoring may focus on the ecological effectiveness of a restoration project, or simply on compliance of the project in implementing the project plan (i.e., was the planned amount of soil moved, trees planted, etc.). An emerging focus of restoration design includes developing methods to evaluate the efficacy of riparian restoration at broader spatial and temporal scales than previously explored (Hausner et al., 2018). In a review of scientific literature focused on

riparian restoration monitoring, González et al. (2015) found that monitoring occurred predominantly for single projects with narrow goals at small spatial scales (reach-scale or smaller) over short time frames (< 6 years). Funding for effectiveness monitoring can be scarce, particularly for long-term processes like disturbance regimes, ecological succession, and community changes. Regional assessments of riparian condition and recovery actions are rare. To enhance the effectiveness of applied riparian restoration efforts, there is a need to implement rigorous long-term experimental designs, with projects that offer comparisons among methods to identify failures or successes (González et al., 2015).

New tools are being developed that use fine-scale spatial data and analyses over a long time-scale to help inform and guide riparian restoration planning (Salo and Theobald, 2016; Macfarlane et al., 2017a,b; Hausner et al., 2018). Recent advances allow mapping of changes in riparian vegetation composition, structure, and spatial extent at new scales (Dufour et al., 2013). Extensive databases for data sharing are being developed for large areas, such as the Colorado River Basin (Woodward et al., 2018). New approaches to quantify land-use effects on riparian vegetation structure are also being developed (Wasser et al., 2015). These emerging research frontiers can guide restoration efforts to support riparian function from a holistic watershed-scale perspective that incorporates both ecological and social needs.

Abstract

Groundwater is an essential life-sustaining resource for billions of people worldwide. It is also a critical backstop during drought when surface water supplies are reduced. But unsustainable depletion of groundwater is now documented on both local and global scales. Climate change will exacerbate these problems. Higher temperatures and more extreme droughts will alter the timing and availability of surface water increasing reliance on groundwater. At the same time groundwater recharge will be reduced limiting supplies for consumptive use and for ecosystems. The net effect of climate change on groundwater depends not only on changing climatic conditions or the physical attributes of a region, but also on human actions and management decisions. Researchers, managers and policy makers involved with and responsible for groundwater stewardship are attempting to develop robust and innovative modeling tools, policies and management strategies to develop the capacity of individuals, groups, or organizations to adapt to the physical and social changes anticipated under climate change. Examples include: the development of modeling tools, an increase artificial recharge and recycled water, incentives to reduce demand, and the development of local drought reserves.

Introduction

Groundwater is an essential life-sustaining resource for billions of people worldwide ([Giordano, 2009](#)). It is also a critical backstop during drought when surface water supplies are reduced. Where extraction rates exceed natural recharge rates the problem is unsustainable depletion of groundwater, now documented on both regional ([Rodell et al., 2009](#)) and global scales ([Wada et al., 2012](#)).

Climate change will exacerbate these problems. Scientists project higher temperatures and more extreme droughts by the end of the 21st century that will alter the timing and availability of surface water, and more individuals and sectors will look to groundwater as a source of supply ([Foster and MacDonald, 2014](#)). At the same time groundwater recharge will be reduced limiting supplies for consumptive use and for ecosystems. Important issues are how the more extreme droughts projected under climate change will

interact with the hydrogeophysical characteristics of a groundwater basin to affect groundwater storage, and what management practices are being used to support groundwater sustainability and security.

The Groundwater Resource

Groundwater represents about 30% of available freshwater on the planet, and it is critical in regions with limited or no surface water supplies (Bovolo et al., 2009). It frequently has a higher storage capacity and is of higher quality than surface water (Kundzewicz and Döll, 2009). It is also less subject to seasonal or interannual variation, making it more reliable than surface water sources. Groundwater also sustains wetlands and riparian ecosystems in humid regions, and unique aquatic ecosystems in more arid and coastal environments.

Groundwater is stored in the sediment pores and fractures beneath the land surface in unconfined, confined and semi-confined aquifers. Between the land surface—including the soil, and the water table—the top level of groundwater, is the vadose or unsaturated zone. Rainfall and applied water infiltrate through the vadose zone down to the water table, and they ultimately recharge groundwater (Fig. 1). A physical definition of groundwater includes soil water, deeper vadose zone water, and unconfined and confined aquifer water.

Precipitation that falls onto the land can infiltrate into the ground to become groundwater. If the water meets the water table it can move both vertically and horizontally. Water moving downward can also meet more dense and water-resistant nonporous rock and soil, which causes it to flow in a more horizontal fashion, generally toward streams, the ocean, or deeper into the ground.

The characteristics of aquifers and confining layers of subsurface rocks (which water has a difficult time penetrating) determine the directions and speed of groundwater movement. Subsurface geologic formations and their arrangements both influence aquifer interconnections and the patterns of hydraulic conductivity that shape aquifer flows (Fogg, 1986). Groundwater movement (Fig. 2) is driven by pressure and occurs in the zone of saturation.

As unconfined aquifers are nearer to the land surface than other formations, they can be recharged by the infiltration of precipitation or other surface water. Confined aquifers are often layered between geologic formations called *aquicludes*, which almost completely obstruct flow, or *aquitards*, which are less permeable and restrict but still allow flow (Harter, 2003).

Recharging aquifers is critical to avoiding the depletion of aquifers over time where groundwater is withdrawn for consumptive use. While precipitation is the major source of groundwater replenishment, recharge is a complex process that is affected by the properties of land, climate, and human activities such as irrigation and pumping (Meixner et al., 2016). Geology and geomorphology (topography, soil, and vegetation) of an area can affect the location and timing of recharge. For example, crystalline metamorphic and igneous rock formations have very small permeability so that any recharge water flows mostly through fractures and faults (Davis and DeWiest, 1966). Basaltic and volcanic formations have more porous zones between lava flows or in lava tubes that can receive direct recharge from precipitation and snowmelt (Fram and Shelton, 2015). Finally, water temperatures can also affect recharge infiltration.

Groundwater Withdrawal Impacts

Groundwater use has frequently resulted in extraction rates exceeding natural recharge rates affecting groundwater flow and storage (Fig. 3).

Fig. 1 Groundwater. USGS.

Fig. 2 Groundwater flow. USGS.

Fig. 3 Pumping effects on groundwater flow. USGS.

When pumping exceeds recharge, basins can become significantly overdrafted and exhibit long-term groundwater depletion and loss of storage (Gleeson et al., 2010). Satellite data shows that several of the world's largest aquifers are in overdraft and nearing depletion. Fig. 4 illustrates groundwater storage trends for Earth's 37 largest aquifers from a UCI-led study using NASA GRACE data (2003–13). Of these, 21 have exceeded sustainability tipping points and are being depleted, with 13 considered significantly distressed, threatening regional water security and resilience. An estimate of groundwater depletion for most of the globe showed that West Asia, the central United States, northwestern India and northeastern China are among the areas showing the most serious loss of storage (Siebert et al., 2010; Wada et al., 2010a,b).

Groundwater depletion can lead to subsidence, seawater intrusion and depletions of interconnected surface water.

Subsidence

Subsidence is defined as a decline in the elevation of the land surface. In parts of California and south-central Arizona, subsidence of land damages buildings, pipelines, canals, highways, and other facilities. Subsidence results from the force of gravity operating with the lowering of the water level or the potentiometric surface of water in a confined aquifer. Subsidence may deprive the aquifer of the ability to recharge, even when water is forcibly injected into wells, thus permanently limiting the capacity of the ground to store water for future.

limits of groundwater that can be withdrawn without unacceptable impacts (Ostrom et al., 1999). CPRs create specific governance challenges. Establishing groundwater rights is complex, with groundwater being extracted by widely dispersed and numerous pumps overlying an aquifer. Moreover, different actors drawing from the same basin may have competing interests, opinions, aspirations, and power positions (Bouarfa and Kuper, 2012). Empirical studies found that interdependence, trust, reciprocity, cooperation and connectedness of individual actors are key in sustaining CPR institutions (Ostrom, 1990, 2010). Other important institutional factors include transparency and accountability, financial viability, and strong commitment by government (Ostrom, 2010; Meinzen-Dick et al., 1997; Megdal et al., 2015). But inclusion and representation can be limited and contested (Cleaver and De Koning, 2015).

These governance challenges have led to inadequate reductions in groundwater extractions in most countries despite attempts to regulate groundwater use (Shah, 2009; Giordano, 2009; De Stefano and Lopez-Gunn, 2012; Frija et al., 2015). In many semi-arid and arid latitudes, where persistent groundwater depletion is driven by competition over limited and ever-decreasing water resources, there can be accelerated water loss and economic disparities (Famiglietti, 2014a,b). Some governance frameworks have been proposed that address imbalances in groundwater access, as well as who defines the rules that determine access and use, but research on whether and how inequities in access are affected by climate change and drought needs more attention.

Climate Change

Anthropogenic climate change depends on the accumulation of carbon dioxide and other heat-trapping gases (GHGs) emitted from human activities in the atmosphere. Climate changes can be projected under different emission scenarios, or representative concentration pathways (RCPs), and global climate models (GCMs) use different RCPs to project future climate conditions.

Climate change has the potential to produce anomalies in temperature and precipitation that will alter atmospheric features of the global hydrologic cycle through greater evaporation, sea-level rise, melting glaciers and ice caps, changing rainfall patterns, and extreme weather events (IPCC, 2014). Already observable effects of global climate change on the environment include shrinking glaciers, earlier break up of ice on rivers and lakes and shifts in plant and animal ranges (NASA, 2019).

Temperature

Warming of the climate system is unequivocal, and since the 1950s, many of the observed changes are unprecedented over decades to millennia.

IPCC (2014)

Each of the last three decades has been successively warmer at the Earth's surface than any preceding decade since 1850 (Fig. 5). Continued emissions of greenhouse gases will cause further warming and changes in all components of the climate system. It is virtually certain that there will be more frequent hot and fewer cold temperature extremes over most land areas on daily and seasonal timescales as global mean temperatures increase. Heat waves are very likely to occur with a higher frequency and duration, as will occasional cold winter extremes (Bates et al., 2008; IPCC, 2014). In the United States, what have been once-in-20-year extreme heat days (1-day events) are projected to occur every 2 or 3 years over most of the nation (NASA, 2019).

Extreme Events

Incidents of extreme weather, including flood and drought frequency, are projected to increase as a result of climate change. With rising temperatures, many locations will see a substantial increase in the number of heat waves per year and a likely decrease in episodes of severe cold. Precipitation events are expected to become less frequent but more intense in many areas, and droughts are projected to be more frequent and severe in the 21st century in some seasons and areas due to reduced precipitation and/or increased evapotranspiration as temperatures rise (NOAA, 2018).

While defining an extreme drought is challenging as the effects of drought accumulate slowly over a considerable period of time and may also linger for years after it is over, projections are that globally by the 2090s drought-affected areas are likely to increase. The proportion of the land surface in extreme drought at any one time is also predicted to increase 10-fold from the present (Kundzewicz et al., 2008). Regions such as the U.S. Southwest will see more frequent and intense droughts due to increased heat and changing rainfall patterns, already visible in the Mediterranean, southwestern USA and southern African regions. In 2011, Texas experienced its driest 12 months ever. At the peak of the 2012 drought, 81% of the contiguous United States was under at least abnormally dry conditions. Globally, drought struck several major breadbasket regions simultaneously in 2012, adding to food price instability. In countries already facing food insecurity, cost spikes can lead to social unrest, migration, and famine (Center for Climate and Energy Solutions can be found at: <https://www.c2es.org/content/extreme-precipitation-and-climate-change/>).

Flood frequency and magnitude are also projected to rise by the end of this century in regions experiencing increases in precipitation intensity. The proportion of total rainfall from heavy precipitation events in the mid-latitude land masses and over wet tropical regions are also very likely to become more intense and frequent by the end of this century as global mean surface temperatures increase (IPCC, 2014). There are already statistically significant trends in the number of heavy precipitation events in some regions including the United States, where the Midwest and Northeast saw strong increases in these events. Changes in the near-term, and

Fig. 5 Observed globally averaged combined land and ocean surface temperature anomaly 1850–2012. IPCC (2014). Climate Change 2014: Synthesis Report. *Contribution of Working Groups I, II and III to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change*, Core Writing Team, R. K. Pachauri and L. A. Meyer (eds.). IPCC: Geneva, 151 pp.

at the regional scale will be strongly influenced by natural internal variability. These trends are likely to continue as the planet continues to warm. For each degree of warming, the air's capacity for water vapor goes up by about 7%. An atmosphere with more moisture can produce more intense precipitation events, which is what has been observed (Center for Energy and Climate Solutions, 2019).

Groundwater and Climate Change

Impacts of Climate Change on Groundwater

Climate change, including projected changes in temperature and precipitation, will impact surface water availability and consequently groundwater through changes to runoff and baseflow, and then to recharge (Hatchett and McEvoy, 2017). Higher temperatures under climate change will result in warmer and shorter winters that can increase surface drying and lead to a loss of soil moisture that will affect groundwater recharge. Temperature increases will also lead to more precipitation falling as rain instead of snow in many regions, resulting in an increase in short-term high flows and faster runoff that will also affect groundwater recharge (IPCC, 2014; DWR, 2017). Additionally, the increasing co-occurrence of dry years with warm years will raise the risk of more extreme droughts (IPCC, 2014) that will also reduce groundwater recharge and consequently groundwater storage (Table 1).

Challenges to addressing groundwater impacts under climate change include:

- A mismatch between large-scale global or regional climate models and small- or medium-scale hydrological processes.
- Limited long-term groundwater data and information that impairs investigations of the responses of groundwater systems to climate change (Zhang, 2015).

Managing Groundwater Under Climate Change

The net effect of climate change on groundwater depends not just on changing climatic conditions or the physical attributes of a region, but also on a wide range of human actions and management decisions. Researchers, managers and policy makers involved

Table 1 Climate impacts to groundwater.

<i>Climate changes</i>	<i>Climate impacts</i>	<i>Impacts to groundwater</i>
Temperature increases	Surface drying-loss of soil moisture	Recharge reduced
Precipitation	More rain and less snow with more short-term high flows and faster runoff	Recharge reduced
More frequent and intense droughts	Reduced surface supplies increased groundwater withdrawals	Storage reduced
Sea level rise	Seawater intrusion	Storage reduced

with and responsible for groundwater stewardship are attempting to develop robust and innovative modeling tools, policies and groundwater management strategies by building the capacity of individuals, groups, or organizations to adapt to the physical and social changes anticipated under climate change (Huntjens et al., 2011).

Modeling tools

Modeling tools for groundwater planning and policy evaluation under climate change are essential for assuring that groundwater levels do not experience long-term declines.

To incorporate the social and physical complexity of groundwater management under climate change, researchers are integrating modern simulation methods with management tools based on physical, institutional, environmental, and economic metrics that reflect decision-making objectives (Gorelick and Zheng, 2015). Examples include optimal groundwater pumping strategies that can control a shallow water table (Barlow et al., 1996); optimal cropping, reservoir release, and groundwater management policies can be used to maximize profit Schoups et al. (2006); and a complex agricultural hydro-economic model that can be used to maximize annual farming benefits subject to hydrologic relations (Maneta et al., 2009). Agent-based models (ABM) can be a versatile approach to represent a coupled human-natural system to define the relationships between simple individual behaviors, collective structures, and interactions with the environment (Macy and Willer, 2002).

Determining sustainable thresholds for groundwater aquifers

A minimum threshold can be defined as the quantitative value that represents the groundwater conditions that when exceeded may cause long-term groundwater depletion and concomitant undesirable impacts in a basin. To establish a minimum threshold it is necessary to first determine a basin's inflows and outflows and then determine a threshold that will avoid long-term groundwater declines. This is generally called the sustainable yield of the basin. While the earlier concept of safe yield emphasized aquifer dynamics (Bredehoeft, 1997; Kalf and Woolley, 2005), sustainable yield also incorporates societal inputs regarding what are considered unacceptable (Alley and Leake, 2004; Gleeson et al., 2010). Both determining a water budget and calculating the sustainable yield of a basin are complex and challenging processes that can require modeling studies and fieldwork, along with a definition of unacceptable impacts from pumping (Rudestan and Langridge, 2014).

To establish a minimum threshold for groundwater levels under climate change, it is necessary to determine the protective groundwater levels necessary to avoid defined unacceptable impacts. Protective levels are often averaged over a reasonable time period to try to accommodate variability in precipitation. It is also necessary to calculate an amount needed in storage to avoid declining groundwater levels during a prolonged and/or intensive drought that are not likely to recover over the long term. To do this, it is first necessary to specify the degree of drought risk. Combining a range of drought lengths in years with a range of drought intensities can provide metrics for potential target droughts. Additionally, the identification of past historical droughts can be used to determine risk for a specific location. The effect of future climate change on any increase in drought severity or frequency of a similar future drought also needs to be considered (Langridge and Daniels, 2017).

Recharging aquifers

Water in aquifers is the most effective strategic weapon against drought.

Army Corps of Engineers (1993)

Recharging aquifers is essential to sustaining a groundwater aquifer over time and to having a groundwater reserve that can be used during drought when surface supplies are limited. It can occur naturally through precipitation that infiltrates into the ground. Recharge can also happen when water is pumped or injected into wells or spread over a land surface to allow it to seep into the aquifer. The term managed aquifer recharge (MAR), also known as aquifer storage and recovery (ASR), is defined as "intentional storing and treatment of water in aquifers' frequently for later recovery or environmental purposes" (Gale and Dillon, 2005). MAR/ASR techniques include surface spreading basins, vadose zone dry wells, and direct injection to recharge aquifers using wells. This approach can be utilized to meet municipal and agricultural water demands in water-scarce regions, as well as assist in the reuse of wastewater. Importantly groundwater in recharged basins can serve as a buffer during periods of drought and changing or variable climate.

Multidisciplinary approaches that incorporate the necessary geophysical and hydrological information, and information on stakeholder/community engagement in program implementation and success, as well as economic and financial analysis are important components for MAR/ASR success (see [Megdal and Dillon, 2015](#)). These include market price, alternative cost, marginal product value, damage cost avoided, contingent value methods, defensive (insurance) value, and environmental value of in situ groundwater. [Maliva \(2014\)](#) notes that costs for drinking water supplies that are typically half the costs of brackish water desalination.

Additionally, implementing MAR/ASR programs requires obtaining water for active recharge. Approaches include supply-side—where groundwater managers attempt to search for new water supplies including from recycled water, desalinated water and rainwater capture, and demand side—where the focus is on controlling groundwater withdrawals.

Increasing supply

Current management approaches to increase supply frequently involve surface storage infrastructure including large multi-purpose dams, small-scale dams, weirs, irrigation systems, rainwater harvesting cisterns, or interbasin transfer schemes. Large reservoirs were built around the world for the storage of surface water. Along with social and environmental concerns, the impact of increasing temperatures and more extreme events will reduce water inputs into these large storage facilities under climate change.

Supply side approaches can also include new wells, the deepening of existing wells and increased groundwater withdrawals, but this approach can negatively affect long-term groundwater storage that could be available during drought.

Additionally, while conservation and water use efficiency are frequently promoted as a demand reduction approach, with suggestions for adequate financial investment in water-saving technology and economic instruments to encourage reduced water consumption ([Foster and Garduño, 2013](#)), it can also increase demand in the future if be saved water is primarily used for new development.

Supply side approaches

- Expand recycled water facilities and use
 - Develop aquifer storage and recovery systems (ASR/MAR) using recycled water
 - Increase storage capacity by building reservoirs and dams
 - Desalinate seawater
 - Expand rainwater capture and storage
 - Remove invasive nonnative vegetation from riparian areas
 - Develop strategies to avoid groundwater loss from contamination
-

Reducing demand

While most groundwater management strategies focus on increasing supply, demand management is also critical to preventing groundwater overdraft and assuring that groundwater is available during drought. It has become an important global policy element for sustainable groundwater management under climate change, and is acknowledged by the World Bank, Asian Development Bank, USAID, GTZ and other international as well as national organizations. However, demand reduction, including limiting withdrawals, is less employed, frequently contested ([Hoogesteger and Wester, 2017](#); [Langridge et al., 2016a,b](#)), and can be difficult to implement with considerable legal and administrative issues.

Demand side approaches

- Establish permit systems or other regulatory or adjudicative restrictions on withdrawals
 - Expand use of economic incentives (e.g., water replenishment fees, metering, and pricing) to encourage reduced withdrawals
 - Reduce water demand for irrigation by changing the cropping calendar, crop mix, irrigation method and area planted
 - Increase incentives to reduce water demands for landscaping
-

Quantitative restrictions are frequently employed to control or influence the amount of water used. Mechanisms and strategies can be developmental, technical, distributive, or financial and market based. Examples include withdrawal and use permits, drilling bans, establishing a water rights system with assigned volumes, electricity pricing, replenishment fees and pumping taxes, and the regulation of drilling companies. Market mechanisms for water trading and sales are also utilized. These can have varying degrees of success in reducing drought vulnerability. This is particularly the case where groundwater use is intensive, and there has been mixed success in using demand management to reduce groundwater extractions ([Shah, 2009](#)).

Conjunctive use of surface and groundwater

Conjunctive use programs typically involve either substitution of surface water in lieu of groundwater pumping, or underground storage of surplus surface water in wet periods for subsequent withdrawal in times of scarcity. The aquifer provides storage for surface water that can be drawn on depending on need. Conjunctive use of surface water and groundwater can enable aquifers to recharge and help to mitigate the water supply stress in responding to climate change and drought.

Optimization models have been proposed for conjunctive use of surface water and groundwater primarily for planning cropping patterns and irrigation water management (Zhang, 2015). Earlier models failed to consider the impacts of future climate change, but recent research is attempting to incorporate climate change impacts into the planning and management of conjunctive water use (Hanson et al., 2012; Hoekema and Sridhar, 2013; Pingale et al., 2014).

Creating a groundwater drought reserve

Establishing a local groundwater drought reserve can mitigate the risk of water shortfalls during an extreme drought under climate change. This can be done by estimating the water shortfall under a range of potential droughts as well as how much water can actually be extracted without unacceptable impacts. Additionally, water demands during a drought generally increase, but some water usage curtailment may also be instituted. Subtracting anticipated water demands during a drought from likely supplies provides the shortfall for specified drought years. The sum of these shortfalls across the duration of the target drought provides the total drought water shortfall. A drought reserve would need to accommodate this quantity to protect against unacceptable impacts for a specified target drought (Fig. 6: Langridge and Daniels, 2017).

Water markets, water transfers, and groundwater banking

Water markets enable the temporary, long-term, or permanent transfer of the rights to use water in exchange for compensation. Water transfers can enable the movement of water to places of critical need, especially during a drought. Because most water is used for irrigation globally and in California, water is frequently leased or sold by farmers or irrigation districts, who transfer/market water to other farmers with scarce supplies and higher value crops, to growing cities or to water providers that supply cities, and to environmental programs. Transfers are often used for “conjunctive use” of groundwater and surface water.

While often a market transaction between a willing buyer and a willing seller, it is also a negotiation with a number of parties with important and legitimate interests in the water that need to be accommodated. Transfers require an appreciation of the complexities of water as a public resource that render it distinctive from other commodities, including the issue of distributive equity. If climate change influences the distribution of water then, indirectly, the rules regarding groundwater access and ownership may influence the impacts of climate change and drought on humans.

Groundwater information systems

Recent developments in studying groundwater under climate change include using satellite measurements of groundwater storage and levels (Famiglietti, 2014a,b; Van Loon et al., 2017; Rodell et al., 2018; Massoud et al., 2018). The Gravity Recovery and Climate Experiment (GRACE) is one such 15-year satellite mission to monitor and study changes in the earth’s water system, of which groundwater is a component (Famiglietti, 2014a,b; Rodell et al., 2018). Scientists also use it to highlight regions where continued monitoring is essential for quantifying impacts to the hydrologic cycle from climate change. Where monitoring wells are absent,

Fig. 6 Example of Protective and Reserve Levels Compared to Current Levels—Data from Soquel Creek Water District 2009. Langridge, R., and Daniels, B. (2017). Accounting for climate change and drought in implementing sustainable groundwater management. *Water Resources Management* 31(11), 3287–3298.

and/or data are missing, the deployment of these and other additional geophysical methods offer an avenue to support evidence-based groundwater management and decision-making.

Climate Change and Groundwater in California

California exemplifies the increasing global water supply crisis, exacerbated by rapid population growth in some of the driest regions and limitations of an energy-demanding and over-allocated water system.

Temperatures vary depending on latitude, elevation, and proximity to the coast. The coastal regions, Sierra Nevada foothills, and much of the Central Valley have a Mediterranean climate, with warmer, dry weather in summer and cooler, wetter weather in winter (Fig. 7). Coastal areas have substantially cooler summers, moderated by the influence of the ocean. California also has high annual variability in rainfall with more rain in the north than in the south, almost no rain in the summer, and periodic droughts. Tree-ring studies show that in the past there were often long periods of dryness sometimes followed by several wet years (Griffin and Anchukaitis, 2014) (Fig. 8).

During drought, groundwater is an essential component of California's water supply providing ~60% of the state's demand. The problem is that groundwater pumping increases during drought and exceeds replenishment in many basins resulting in long-term groundwater level declines (Fig. 9). Moreover, there is no permit system to withdraw groundwater in the state and landowners overlying a groundwater basin have a right to pump with limited restrictions, contributing to the overdraft and concomitant negative impacts including overdraft, seawater intrusion, land subsidence and water quality degradation. Since 2010, some areas of the state already see "alarming declines in groundwater levels," with negative impacts that include irreversible land subsidence, poor water quality, reduced surface flows, ecosystem impacts, and the permanent loss of capacity to store water as groundwater (DWR, 2015a,b). Additionally, many overdrafted aquifers contain high levels of contamination (DWR, 2015a,b).

Climate change will exacerbate these issues. Projections are that temperatures will rise throughout the state during the 21st century (Cayan et al., 2008:21), and the 2014 temperatures were the warmest on record for the state (Office of Environmental Health Hazard Assessment, California Environmental Protection Agency, 2018). This will exacerbate drought conditions in the future and increase groundwater storage deficits.

Fig. 7 Shaded relief map of California. National Atlas.

Fig. 8 Seasonal rainfall in Los Angeles, California. rssWeather.com.

Fig. 9 California Drought and Groundwater. Famiglietti, J. S. (2014a). Epic California drought and groundwater: Where do we go from here? National Geographic <https://blog.nationalgeographic.org/2014/02/04/epic-california-drought-and-groundwater-where-do-we-go-from-here/>; Famiglietti, J. S. (2014b). The global groundwater crisis. *Nature Climate Change* 4(11), 945–948.

The state is also heavily reliant on snowmelt from the Sierra Nevada and Trinity mountains that is captured, stored and then imported primarily to areas of Southern California via two large water projects, the Central Valley Project (CVP) and the State Water Project (SWP). Projections of warmer and shorter winters with more precipitation falling as rain instead of snow and more short-term high flows and faster runoff, will reduce this surface water storage (DWR, 2017) thereby affecting the reliability of the imported water that is used for active and in-lieu groundwater recharge by many basins. Under end-of-century business-as-usual warming, in a major drought, the Sierra Nevada is projected to lose 85% of its snow, and even in a wet year it is likely to lose 2/3rds of its snow

Fig. 10 Historical and projected snowpack under two different climate change futures, from the California Water Plan Update 2013.

(Berg and Hall, 2015). Under these conditions, State Water Project (SWP) deliveries will decrease and will be more costly in the future (Fig. 10) (Tanaka et al., 2006; Harou et al., 2010).

In 2012–16, California experienced the most severe drought in the last century with accumulated moisture deficits worse than any previous continuous span of dry years. Record high temperatures and long-term warming trend intensified the impacts of limited precipitation (Berg and Hall, 2015; Diffenbaugh et al., 2015), and groundwater levels in many basins decreased significantly (DWR, 2017).

The Sustainable Groundwater Management Act (SGMA)

To address these problems, in 2014 the California legislature passed the Sustainable Groundwater Management Act (SGMA) (AB 1739, SB 1168 and SB 1319) that for the first time established new mandatory rules for 127 high and medium priority groundwater basins with declining groundwater levels. Groundwater users in these basins were required to form groundwater sustainability agencies (GSAs) and to develop groundwater sustainability plans (GSPs) with the state evaluating local GSPs and their implementation.

The SGMA defines “sustainable groundwater management” as: “The management and use of groundwater in a manner that can be maintained during the planning and implementation horizon without causing undesirable results,” defined as:

- Chronic lowering of groundwater levels indicating a significant and unreasonable depletion of supply and reduction of groundwater storage.
- Significant and unreasonable seawater intrusion, degraded water quality, and land subsidence that substantially interferes with surface land uses.
- Surface water depletions that have significant and unreasonable adverse impacts on the beneficial uses of surface water.

SGMA requires the incorporation of climate change assumptions into the development of projected water budgets, and GSAs are including traditional approaches to manage groundwater basins in their GSPs.

New Approaches and Management Trends

Although SGMA does not include explicit incentives for proactive management of groundwater to address the more extreme droughts projected under climate change, GSAs are developing new ways of providing recharge and establishing drought reserves to address future climate change. New approaches to recharge include using flood flows to both irrigate agriculture as well as to recharge groundwater basins, illustrated in [Fig. 11](#) ([Kocis and Dahlke, 2017](#)).

The use of, recycled water continues to increase ([Pezzetti and Balgobin, 2015](#)), and there has been an increase in desalination and stormwater capture projects ([Langridge et al., 2018](#)). The SGMA allows for charging fees for pumping in excess of allocations, and approaches to reduce pumping are being incorporated into many GSPs. Several basins have developed local groundwater drought reserves ([Langridge and Fencil, 2019](#)) ([Table 2](#)).

Notably, California became the first state in the country to adopt a Human Right to Water. It states that: “every human being has the right to safe, clean, affordable and accessible water adequate for human consumption, cooking and sanitary purposes, and state agencies have a duty to consider this as they establish policies and regulations.”

Final Thoughts

Given the world’s reliance on groundwater and threats posed by drought, there is an increasing need to understand the barriers and opportunities to managing groundwater sustainably under future climatic changes and ever present drought conditions. Vulnerability to drought and climate change is not geographically bounded by the groundwater basin, for example, but is affected by choices and conditions on multiple scales ([Adger et al., 2009](#)). This is especially true in California, where melting snowpack is captured in reservoirs and transmitted throughout the state. But what renders any region’s groundwater vulnerable to climate change and drought in a given geography are both physical teleconnections such as ENSO events, Arctic Sea ice, and ocean surface temperatures that can alter the experiences and severity of drought; and social teleconnections including global economic forces, education and knowledge flows, and legal and governance structures that shape capacities and barriers to adaptation to a future climate ([Moser and Hart, 2015](#)).

Table 2 Management trends.

Strategies	Management trends
Conservation	1976 drought—Voluntary conservation 2007–09 drought—Mandated conservation SBX-7-20x20x20 2012–14 drought—EOB-29-15: mandatory 25% reduction for urban users. Rescinded in 2017 New bills (AB 1668 and SB 606) in 2019 will direct water agencies to limit customers' indoor water use to an average of 55 gal per person each day. The goal is reduced to 52.5 gal by 2025 and 50 gal by 2030
Recycled water use ~190,000 AF	Recycled water use 1970: ~175,000 AF 1987: ~267,000 AF 2009: ~669,000 AF 2015: ~714,000 AF
Financial incentives to limit withdrawals	Increasing use to comply with SGMA
Planning	Move from voluntary sustainable groundwater management to mandatory sustainable groundwater management plans
Local drought reserves	Increasing use of local groundwater drought reserves

Source for the information on recycled water use: Pezzetti, T., and Balgobin, D. (2015). California recycled water use in 2015, https://water.ca.gov/LegacyFiles/recycling/docs/2015RecycledWaterSurveySummary_Slunits.pdfhttps://www.water.ca.gov/LegacyFiles/recycling/docs/2015RecycledWaterSurveySummary_Slunits.pdf.

According to the IPCC (2014), the array of potential adaptive responses available to human societies is very large, including technological, behavioral, and managerial strategies. While traditional drought adaptation strategies are known and developed, the effectiveness of various options to fully reduce risks for vulnerable groundwater-stressed areas during extended and intense drought periods nevertheless remains an ongoing challenge for the future.

Abstract

Glaciers participate in the global carbon cycle. They collect, produce, transform, store and release carbon. A part of this carbon is ancient and is “captured” by the glacier in two ways. Firstly, a growing glacier may override an ecosystem and lock organic matter long enough to become ancient. Secondly, the surface of even remote glaciers “collect” aerosols containing ancient carbon. These aerosols are combustion products of fossil fuels such as coal, oil or gas. Sooner or later, compounds containing ancient carbon are released from the glacier, and these compounds can be bioavailable. It has been shown that ancient carbon can be assimilated into food webs in glacier forelands, in glacial rivers, and in marine environments. Living invertebrates may achieve a radiocarbon age of several thousand years. Increased glacier melting due to climate change will increase the flow of ancient carbon to various food webs and may disturb radiocarbon dating of sediments.

Introduction: Glaciers Matter

Glaciers and permanent snowfields are “cold deserts” with little biological activity. Still, their presence and dynamics have several ecological effects. Containing about 70% of the Earth’s freshwater, they contribute substantially to the global hydrological cycle. During the last decades, it has been clear that glaciers also play a role in the global carbon cycle. Ice and permanent snowfields cover as much as 11% of the terrestrial areas (National Snow & Ice Data Center), and this large surface accumulates short- and long-transported (windblown) carbon, organic as well as inorganic. Glacier surfaces may also produce organic matter through photosynthetic activity in so-called cryoconite holes. Organic material collected, produced or transformed on the glacier surface can be preserved within the ice for a long time. Furthermore, glaciers may contain overridden soil and vegetation. Sooner or later, glacier-locked carbon is released by melting water at the glacier front and transported away in glacier rivers. In other words, glaciers collect, produce, transform, store and released carbon. They are ecosystems housing unique life adaptations of cold-adapted and cold-loving microorganisms, both autotrophs and heterotrophs (Hodson et al., 2008; Stibal et al., 2012; Hood et al., 2015). Glaciers are now recognized as a biome—the cryospheric biome (Anesio and Laybourn-Parry, 2012).

Glaciers are “climate trackers” (Fig. 1): As climate changes, so do glaciers (Lowell, 2000; Oerlemans, 2005). Increased glacier melting will increase carbon release via glacial river systems. In a review paper, Hood et al. (2015) estimated that across five continents, mountain and polar glaciers contain about 6 petagrams (Pg) of organic carbon. Most of this is stored within the Antarctic ice sheet. However, the annual release of ice-locked organic carbon occurs mainly from the Greenland ice sheet (especially particulate organic carbon) and from mountain glaciers (especially dissolved organic carbon). Due to climate change, glaciers are shrinking, and glacier mass loss is responsible for about 13% of the annual release of dissolved organic carbon from glaciers. Based on an assumed accelerated melting rate, the cumulative loss of glacial dissolved carbon by 2050 might amount to half of the annual release of dissolved organic carbon from the Amazon river. Glaciers link terrestrial and aquatic carbon transport, including land-to-ocean fluxes.

Fig. 1 Glaciers matter in the global carbon cycle. They collect, produce, transform, store and release carbon. A part of this carbon may be ancient. Glaciers are also “climate trackers”, releasing increased amounts of water and carbon. This glacier snout is part of the Hardangerjøkulen glacier in South Norway. During 12 years, from 2005 to 2017, the glacier front receded 155 m, leaving the barren area seen on the picture. Photo: Sigmund Hågvær.

A somewhat surprising discovery during the last decades is that carbon released by glaciers may be very old, up to several thousand years. After release, this ancient carbon can be assimilated by microorganisms and invertebrates in the glacier foreland and support early colonization of life on newly deglaciated areas. Ancient carbon is also transported away and assimilated by various organisms in glacial river systems—and even in the ocean (Bardgett et al., 2007; Hood et al., 2009; Stubbins et al., 2012; Singer et al., 2012; Hågvær and Ohlson, 2013; Spencer et al., 2014a,b; Fellman et al., 2015a,b; Hågvær et al., 2016).

Assimilation of ancient carbon results in a paradox: Living organisms, for instance insects, can achieve a radiocarbon age of several thousand years (Hågvær and Ohlson, 2013; Hågvær et al., 2016).

This review will discuss the sources of ancient carbon, how is it captured and stored by glaciers, and the ecological role of ancient carbon after being released.

Two Main Sources of Ancient Carbon

There are two main ways in which a glacier may become a store of ancient carbon. The first is easy to conceive: If the glacier grows and overruns vegetation and soil, the carbon in the captured ecosystem may be locked up beneath the glacier long enough to become ancient. The second is cryptic but important: The glacier surface may receive tiny aerosol particles which are the result of incomplete combustion of fossil fuels like coal, oil or gas. These particles are “ ^{14}C -dead”, which means that they contain mainly the ^{12}C isotope and has a very high radiocarbon age.

Overriding Vegetation and Soil

During the 8–10,000 year period after the termination of the last ice age, the size of individual glaciers has varied according to climate changes. For instance, the present Norwegian glaciers are not remnants of the large “ice age glacier”, which once covered the whole country, as today's glaciers have been periodically absent (Nesje et al., 2008). The latest growth period for Norwegian glaciers terminated around 1750, at the end of a cold period called “the little ice age”. Characteristic “1750-moraines” are common, and there is documentation from around 1750 that certain mountain farms were abandoned or even destroyed due to the advancing glacier front (Foss, 1802).

The ice mass of glaciers is to a certain degree plastic, and organic matter held by the glacier is finally expelled at the edge. For instance, during the last decades, Norwegian glaciers have receded strongly and released woody items like bow and arrows from thousands of years old hunting cultures. These items are perfectly preserved and seem freshly made.

Capturing Air-Borne Aerosols

While only certain glaciers contain subglacial, relict soil or vegetation, all glaciers have the ability to capture ancient carbon on their surface. Fine-particulate aerosols can remain airborne for up to 3 months (Druffel, 2004) and are able to contaminate ice sheets in

Fig. 2 Aerosols containing ancient carbon of anthropogenic origin can be deposited on glacier surfaces even in remote areas. The Figure illustrates the glacial organic carbon cycle, including some examples on radiocarbon age. From Stubbins, A., Hood, E., Raymond, P. A., et al. (2012). Anthropogenic aerosols as a source of ancient dissolved organic matter in glaciers. *Nature Geoscience* 5, 198–201.

remote areas (Fig. 2). For instance, in the Juneau Icefield in Southeast Alaska, dissolved organic carbon deposited on snow surfaces consisted mainly of fossil fuel combustion products (Fellman et al., 2015a). Since the industrial revolution, the global atmosphere has been gradually contaminated with aerosol particles carrying ancient carbon. An ice core from an alpine glacier in Switzerland revealed that almost half of the organic carbon deposited in 1940 originated from combustion of fossil fuels, while deeper ice from before 1850 contained virtually nothing of this element (Jenk et al., 2006). Studies of the air quality in Zurich showed that about 30% of the organic carbon in the air was of anthropogenic origin (Szidat et al., 2006). Unsurprisingly, this carbon may be washed out from the air during rain, as shown by Raymond (2005) who found ancient carbon from fossil fuels in rainwater in the Northeastern United States.

Ancient Carbon Beneath, Upon or Within Glaciers: Case Studies

Ancient Carbon Beneath Glaciers

A direct way of dating overridden organic material is to bore through the ice and collect organic matter beneath the glacier. Two case studies from Svalbard illustrate this. Frozen soil and vegetation were found 30–35 m below the present-day surface of the Longyear glacier. Interestingly, this soil system contained microbes which had survived more than 1100 years in a subglacial, permafrozen state. Before that, the actual area was ice-free for at least 800 years, but then overrun by a growing glacier (Humlum et al., 2005). The microbial community structure and ecology was also studied in subglacial sediments of two other Svalbard glaciers (Kastovska et al., 2007). Even here, viable bacteria, cyanobacteria and microalgae were detected. Newly deglaciated soils were similar in microbial structure but different from vegetated sites. These results suggested that subglacial microorganisms retained the ability to proliferate if conditions improved. A diverse microbial life beneath a high Arctic glacier was also documented on Ellesmere Island, Canada (Skidmore et al., 2000). Clearly, organic compounds in overrun vegetation and soil may not only be stored for a long time but can be slowly modified by cold-tolerant microorganisms, although temperature is close to zero.

Surface-Collected Ancient Carbon and Supraglacial Processes

Glacier surfaces often appear dirty. They receive both ancient carbon via aerosols and modern carbon via wind-blown debris. Stibal et al. (2010) studied organic matter content and quality in debris on the surface of the Greenland ice sheet. Three key processes influenced the carbon cycling here: eolian (wind) input of microbial inoculum and nutrients, in situ biological carbon transformation (photosynthesis and decomposition), and the wash-away of supraglacial debris by meltwaters. Glacier surfaces are to a varying degree a habitat for biological production. On a Svalbard glacier, Stibal et al. (2008) found that microbial primary production was insignificant in comparison with allochthonous organic carbon input. However, from Greenland, Bhatia et al. (2010) concluded that the majority of supraglacial dissolved organic matter originated from autochthonous microbial processes on the ice sheet surface. A considerable proportion of protein-like compounds were observed in the supraglacial samples.

Glacier surfaces may have a surprisingly high microbial activity which influences the global carbon cycle (Anesio et al., 2009; Hodson et al., 2010). Algae, bacteria and viruses may thrive in so-called cryoconite holes, which can cover 0.1–10% of the glacier surface. These are small, water-filled depressions in the ice (usually less than 1 m in diameter and less than 0.5 m deep). They are created when solar-heated inorganic and organic debris—including dark aerosols—melts into the ice and gradually aggregate. Studies on cryoconite holes in Svalbard, Greenland and the European Alps revealed a high microbial activity, although temperatures were close to 0°C. It was estimated that cryoconite holes in glaciers outside Antarctica could fix as much as 64 Gg of carbon per year.

In cryoconite holes, aerosol particles containing ancient carbon are mixed with new organic matter produced by chlorophyll-containing algae and cyanobacteria. Aerosols can also be chemically transformed by microorganisms and included in new organic compounds. The collective chemical products from these “cryoconite hole ecosystems” can either be stored within the glacier or washed off the glacier surface. In the last case, they can end up within glacier cracks, or be transported away via glacial rivers.

When finally released through melting water, ancient carbon from aerosol particles can be more or less transformed, more or less mixed with other products created in cryoconite holes, and further mixed with rather unchanged in-blown organic material of recent origin. The radiocarbon age of this final mix depends on the relative proportion between ancient and recent carbon and is not “the age of this sample”. We can only say that the higher the radiocarbon age, the more ancient carbon does the actual sample contain. In contrast, if a distinct piece of a plant released from overridden vegetation is analyzed separately (for instance a twig or a tree stem), its radiocarbon age will be true.

Glaciers With Both Overridden and Surface-Collected Ancient Carbon

The following case studies from Greenland illustrate the combined release of ancient carbon from overridden soil/vegetation, and from airborne, surface-trapped particles (Bhatia et al., 2010, 2013). During the early melting season in spring, the release of organic carbon via melt water was considered to stem mainly from the surface of the glacier. A considerable proportion of protein-like compounds probably originated from autochthonous processes on the ice sheet surface. Later in the melting season, there was an increase in lignin-like and other material that probably derived from underlying vegetation and soil. We see that supra- and sub-glacier organic matter can give different signals in the discharged melt water. However, here it must be added that microbial oxidation, which occurred under the glacier, contributed to the release of metabolic products.

Thus, the release of ancient carbon from the Greenland glacier fed not only the foreland and glacier rivers, but was also discharged into marine environments.

Release and Biological Use of Ancient Carbon

Bioavailable compounds released from glaciers may contain ancient carbon. When these compounds are assimilated, for instance by microorganisms, ancient carbon can end up in food chains, either in the glacier foreland, downstream in glacial rivers, or in marine environments. Some examples will illustrate these alternatives.

Occurrence and Use of Ancient Carbon in Glacier Foreland, Supporting Early Succession

In newly exposed glacial “soil”, heterotrophic microbial communities may use ancient carbon before autotrophic succession starts. This was demonstrated in an Austrian glacial foreland, where microbes used both ancient and modern carbon as an energy use during the first 50 years of succession (Bardgett et al., 2007). Also in Svalbard, ancient organic carbon has been documented in glacier foreland soil (Yoshitake et al., 2011).

In front of a melting Norwegian glacier, freshly produced sand and silt contained organic material with a radiocarbon age of 5160 years (Hågvær et al., 2016). This organic material tended to aggregate in depressions, including the bottom of newly created ponds of varying size, some of them less than a square meter large. These ponds turned out to function as “biological oases” (Fig. 3). Sediments of 8-year-old ponds contained dense populations of tube-living chironomid larvae, which had a radiocarbon age up to 3270 years when analyzed with intact gut content. Tipulid larvae collected from the same pond sediments, analyzed after the gut content had been removed, had a radiocarbon age of 1610 years, proving that ancient carbon had been assimilated into their tissue. Larvae may either have digested directly organic compounds containing ancient carbon, or eaten bacteria that had assimilated ancient carbon. These ponds even contained diving beetles, of which both larvae and adults were assumed to feed on chironomid or tipulid larvae. Larvae and adults of diving beetles had radiocarbon ages of 1200, and 1130 years, respectively. The use of ancient carbon in ponds lasted for several decades, since larvae in a 80 year old pond was 350 year “old”.

It has long been recognized that predator invertebrates like spiders and carabid beetles colonize virgin ground like glacier forelands before a visible vegetation is present (Hågvær, 2012; Hågvær et al., 2017). This has been called “the predator first paradox” (Hodkinson et al., 2002). According to ecological theory, a new ecosystem must start with plants, followed by herbivores, and then predators. The paradox has been explained by aerial transport of prey like midges and flies to the virgin ground. Such transport occurs (Coulson et al., 2003; Flø and Hågvær, 2013) but it is only part of the story. Hågvær and Ohlson (2013) and Hågvær et al. (2016) documented another possibility: Local production of prey based on the use of ancient carbon released from the glacier. Following up the case mentioned above, they showed that adult chironomid midges hatching from young ponds had a radiocarbon age of 1040 years. Microscopic studies of gut contents from predatory carabid beetles and harvestmen (Opiliones) revealed that chironomid midges that had fallen to the ground made up a substantial part of their diet (Hågvær and Pedersen, 2015). This transport of ancient carbon from aquatic to terrestrial habitats explained why terrestrial predators among beetles, harvestmen and wolf spiders had radiocarbon ages between 340 and 1100 years (Fig. 4).

The pioneer ecosystem on a newly deglaciated area was supported by three “invisible” food sources (Fig. 5): (1) Ancient carbon assimilated by chironomid larvae in young ponds and transported to terrestrial predators via adult midges. (2) A terrestrial biofilm

Fig. 3 These insects from 7 to 9-year-old ponds contained ancient carbon released by the glacier. (A) In the sediment surface, numerous tubes can be seen, in which chironomid larvae were living. (B) Chironomid larvae, here partly freed from their tubes, had a radiocarbon age of 3270 years. (C) Two predacious larvae of the diving beetle *Agabus bipustulatus* (radiocarbon age 1200 years), and three cylindrical Tipulidae larvae (Diptera) (radiocarbon age 1610 years). (D) Adult predacious diving beetles, *Agabus bipustulatus*, had a radiocarbon age of 1130 years. From Hågvar, S., Ohlson, M. and Brittain, J. E. (2016). A melting glacier feeds aquatic and terrestrial invertebrates with ancient carbon and supports early succession. *Arctic, Antarctic, and Alpine Research* **48**, 551–562.

Fig. 4 Living, but “old”. Four predatory invertebrates living on barren pioneer ground had radiocarbon ages between 340 and 1100 years. Gut contents revealed that they had eaten adult chironomid midges. As larvae, midges had assimilated ancient carbon in young ponds. Some moraines back to 1750 are shown. From Hågvar, S. and Ohlson, M. (2013). Ancient carbon from a melting glacier gives high ^{14}C age in living pioneer invertebrates. *Scientific Reports* **3**, 2820.

containing diatom algae, on which certain pioneer Collembola grazed. (3) Tiny pioneer mosses grazed upon by certain Collembola and beetles. Collembola was not an important food source for predators in the actual site.

Transport and Use of Ancient Carbon in Glacial Rivers

Hood et al. (2009) showed that heavily glaciated watersheds in Alaska transported ancient dissolved organic matter with a radiocarbon age up to 3900 years, all the way to the Gulf of Alaska. The bioavailability to marine microorganisms was highest for the oldest organic matter.

Fig. 5 Ancient carbon (red boxes and arrows) contributes to a pioneer food web on 3–7 year old ground. The flow of chlorophyll-produced carbon is illustrated in green, and the contribution of aerial transported carbon in black. Trophic levels are shown for both freshwater and terrestrial habitats. Chironomid midges hatching from young ponds transported ancient carbon to terrestrial pioneer predators. From Hågvar, S. and Ohlson, M. (2013). Ancient carbon from a melting glacier gives high ^{14}C age in living pioneer invertebrates. *Scientific Reports* 3, 2820.

In 26 glaciers within the European Alps, [Singer et al. \(2012\)](#) studied the molecular composition of ice-locked organic matter, sampled 0.5 m below the glacier surface. Among several molecular clusters, two contained ancient carbon. One molecular group was humic-like with polyphenols from lignin and could represent overridden soil and vegetation. The other molecular group could be combustion products deposited on the glacier surface. The ancient carbon compounds had radiocarbon ages between 600 and 8500 years. They were biodegradable and assimilated in inoculum experiments, indicating that ancient carbon contributed to downstream carbon cycling.

In Southern Norway, a river fed by a receding glacier transported bioavailable ancient carbon ([Hågvar et al., 2016](#)). Chironomid larvae were sampled 0.8, 1.4 and 4.0 km downstream. Their radiocarbon age was 1190, 1260, and 290 years, respectively. In order to avoid possible contamination from nonassimilated matter, their gut content was removed before the analysis. Guts contained few signs of algae, but a lot of small mineral particles. There is a possibility that these might have been ingested during grazing on bacterial biofilm.

[Fellman et al. \(2015b\)](#) showed that dissolved ancient carbon in an Alaskan proglacial stream was assimilated into a food chain, probably starting with an epilithic bacterial biofilm. Second level was grazing chironomid larvae, whose gut content contained fine rock fragments. Third level was predatory, juvenile salmonids.

It should be mentioned that also nonglacial rivers may carry bioavailable ancient carbon. In that case, the ancient carbon is typically derived from peat and captured by the river through erosion. Two cases of eroding tundra rivers can illustrate this, one from Siberia ([Vonk et al., 2013](#)) and one from Alaska ([Schell, 1983](#)). In the Siberian case, bioavailable dissolved organic carbon of more than 21,000 years age was transported downstream and all the way to the coast. In the Alaskan case, old peat particles were assimilated by aquatic invertebrates. Old squaw ducks (*Clangula hyemalis*) feeding on these invertebrates had only 85% modern ^{14}C content, corresponding to an “age” of 1300 years. There are even rivers that contain ancient carbon from both glacier and eroded soils or peat, like the Yukon River basin ([Aiken et al., 2014](#)). [Caraco et al. \(2010\)](#) reported bioavailable ancient carbon in Hudson river, due to erosion in agricultural lands and sewage inputs. Crustacean plankton ingested small-particulate ancient carbon and became highly ^{14}C depleted.

Marine Environments Receiving Ancient Carbon From Glaciers

The Gulf of Alaska is fed by several glacial rivers. They expel dissolved organic matter containing ancient carbon into the marine environment. The ancient carbon is derived mainly from combustion aerosols that have been deposited on the glacier surfaces. The most heavily glaciated watersheds carry the oldest carbon, which is also the most bioavailable. Near-shore marine environments respond with increased growth of bacterioplankton. Due to rapid glacier melting, the delivery of relic carbon to the Gulf is increasing, and this may affect the function and productivity of coastal ecosystems ([Hood and Scott, 2008](#); [Hood et al., 2009](#); [Fellman et al., 2010, 2015a](#)).

Another marine locality receiving considerable amounts of ancient carbon is the coastal waters of Greenland. ^{14}C -depleted organic matter is released by the receding glacier, transported downstream to the coast or washed directly into the ocean ([Bhatia et al., 2013](#)).

Perspectives

Combustion-Derived Black Carbon Accelerate Glacier Melting

Black carbon aerosols deposited on glacier surfaces in Himalaya accelerate ice melting, which in the long run threatens the water supply for billions of people. A study of carbon isotopes in aerosols and snowpit samples showed that about half of the carbon was ancient and derived from fossil fuels, while the other half was due to biomass combustion (Li et al., 2016). Clearly, the human use of fossil fuels has a double effect on glacier melting, both by increasing the global temperature, and by spreading black carbon that absorbs solar heat on glacier surfaces.

Ancient Carbon Enter Contemporary Food Webs

The human combustion of fossil fuels leads to a global spread of ancient carbon through far-reaching aerosols. A part of this ancient carbon is bioavailable and is gradually incorporated in contemporary food webs of various ecosystems. This is especially evident in aquatic environments, both freshwater and marine. A review by Guillemette et al. (2017) stresses that this change in resource utilization may alter food web stability, structure and dynamics of ecosystems. As shown above, ancient carbon may also find the way to terrestrial ecosystems, for instance by midges with aquatic larvae (Hågvar and Ohlson, 2013).

Primary succession on virgin ground in a glacier foreland is fascinating ecology, and still more if ancient carbon can support the process. The presence of young ponds in which chironomid larvae can assimilate ancient carbon was a key factor in the referred example, but more case studies are welcome.

Since ancient carbon released by glaciers can be “pumped” into both aquatic and terrestrial food webs via chironomids, these midges deserve closer ecological studies. It remains to clarify whether bacteria in ponds or rivers represent the first step in the assimilation of bioavailable ancient carbon, or whether chironomid larvae can digest the ancient carbon directly. More studies should also be performed on the possible assimilation of ancient carbon in vertebrate predators like fish or insect-feeding birds along glacial rivers.

A simple way to document release and biological use of glacier-derived ancient carbon is to sample chironomid larvae in glacial rivers and measure their radiocarbon age. Gut contents should be removed before analysis to avoid contamination from nonassimilated matter.

Ancient Carbon Disturbs Radiocarbon Dating

If organisms that have assimilated ancient carbon are included in sediments, for instance as slowly decomposable insect chitin in lake sediments, a future radiocarbon aging of the actual sediment layer will achieve a too high age. Since glacier surfaces are efficient collectors of ancient aerosol carbon and since organisms in glacial rivers are able to assimilate this carbon, lakes and wetlands which belong to glacial watersheds are especially vulnerable to be contaminated by sediments with “too high age”.

Introduction	1
A Glossary of Terminology Used in Freshwater Biology and Management	1
References	8

Abstract

A glossary of more than 220 terms used in reference to freshwater is provided to establish a common base of understanding among workers in this discipline.

Introduction

The Freshwater Biome is rich in concepts and associated terminology. The Biome includes many forms, uses, and distributions of freshwater (Suring, 2020). The usage of the terminology to describe these forms, uses, and distributions may vary over time, geographically, and by discipline. Different meanings of the same words may cause misunderstandings, especially by students in the various fields associated with freshwater and by specialists from other disciplines who may not be familiar with specific uses of terms. As such, it is useful to provide a glossary of current definitions of freshwater terminology to accompany the chapters describing the Freshwater Biome and its management.

The glossary does not intend to provide a review or history of all uses of particular terms, nor how they may be used in fields other than those associated with the ecology and management of freshwater. The glossary excludes terminology specific to the names of species and higher taxa associated with freshwater ecosystems, place names, taxonomy, legal and regulatory terms, and acronyms.

A Glossary of Terminology Used in Freshwater Biology and Management

Term	Definition	References
Ablation	The loss of ice and snow from a glacier system. This occurs through a variety of processes including melting and runoff, sublimation, evaporation, calving, and wind transportation of snow out of a glacier basin.	Molnia (2004)
Acid precipitation	Rainwater or snow containing sulfur and nitrogen compounds and other pollutants associated with industrialization.	Freshwater Information Platform (2019)
Aeolian	Pertaining to the action or effect of wind.	Lincoln et al. (1998)
Allochthonous	Describes material that comes into freshwater systems from outside the system (e.g., organic matter entering freshwater systems from trees).	Maitland and Morgan (1997)
Alluvial deposits (alluvium)	Material such as clay, silt, sand, and gravel deposited by modern rivers and streams.	Freshwater Information Platform (2019)
Amictic lakes	Lakes that do not have a period of overturn because they are perennially frozen.	Lincoln et al. (1998)
Amphidromous	Migration of organisms downstream to an estuary to feed or for growth during short periods, followed by upstream migration.	Lucas and Baras (2008)
Anadromous	Migration by organisms from marine systems to upstream freshwater spawning systems.	Lucas and Baras (2008)
Anchialine	Haline water, usually with restricted exposure to open air, and always with subterranean connections to the sea.	Culver and Pipan (2013)
Ancient carbon	Carbon pulled out of the atmosphere and stored in the bodies of plants hundreds or thousands of years ago.	Dean et al. (2018)
Aphotic	Without light, generally interpreted limnologically as receiving less than 1% of solar irradiance reaching a lake surface.	Lewis (2009)
Aquaculture	Farming of plants and animals that live in water, such as fish, shellfish, and algae.	United States Geological Survey (2019)
Aquatic ecosystem	A community of organisms together with their physical environment organized around a body of water.	Texas Aquatic Science (2013)
Aquatic macroinvertebrates	Macroscopic animals without backbones ("invertebrates") that are large enough to be seen with the naked eye ("macro," e.g., >0.5 mm).	Freshwater Information Platform (2019)
Aquiclude	A barrier that is almost impermeable to water flow between aquifers.	Harter (2003)

(Continued)

<i>Term</i>	<i>Definition</i>	<i>References</i>
Aquifer	A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.	Freshwater Information Platform (2019)
Aquitard	A geological layer or formation which limits the flow of groundwater between aquifers.	Harter (2003)
Autochthonous inputs	Organic matter from within a freshwater system's primary production from algae or periphyton.	McManamay and Jager (2020)
Autotrophy	Self-sustained production of organic matter from inorganic substances.	Schmidt and Hahn (2012)
Bacterioplankton	Bacterial component of the plankton that drifts in the water column of both seawater and freshwater ecosystems.	Pommier (2011)
Benthic	The zone of a lake extending a few centimeters above and below the bottom of the lake.	Lewis (2009)
Benthos	The community of organisms living around surfaces (e.g., sediments, plants) in aquatic ecosystems.	Strayer (2009)
Biome	A major ecological community characterized by distinctive life forms.	Lincoln et al. (1998)
Bioturbation	Sediment mixing caused by the activities of organisms.	Strayer (2009)
Blackwater rivers	Rivers that are rich in humic acids and with low nutrient concentrations.	Lincoln et al. (1998)
Blue water	Fresh surface and groundwater; in other words, the water in freshwater lakes, rivers, and aquifers.	Hoekstra et al. (2011)
Braided river	A braided river channel consists of a network of smaller channels separated by small and often temporary islands called braid bars.	Freshwater Information Platform (2019)
Capture fishery	Capture fishery refers to all kinds of harvesting of naturally occurring living resources in both marine and freshwater environments. On a broad level, capture fisheries can be classified as industrial, small-scale/artisanal, and recreational.	GreenFacts Digests (2019)
Catadromous	Organisms that are reared in freshwater and migrate to the marine environment to spawn.	Lucas and Baras (2008)
Catchment	A natural drainage basin which channels rainfall into a single outflow.	Lincoln et al. (1998)
Cienega	Wetland systems unique to the American Southwest that are wet meadows with shallow-gradient and permanently saturated soils in otherwise arid landscapes.	Hendrickson and Minkley (1984)
Collectors	Organisms that filter and collect smaller particles of organic matter found in the water column and bottom sediments. This organic matter can range in size from 0.01 to 1.0 mm and usually arrives in water columns and benthic sediments as a result of organic matter being broken up by shredder species.	Stumpf et al. (2015)
Colluvial	Colluvial material or colluvial soil is a general name for loose, unconsolidated sediments that have been deposited at the base of hillslopes by rainwash, sheetwash, slow continuous downslope creep, or a variable combination of these processes.	Leopold and Völkel (2007)
Crenobiology	The study of the biology of springs.	Sada et al. (2001)
Crenobionts	Species largely restricted to springs.	Glazier (2009)
Crenophiles	Species that commonly occur in spring habitats but also occur elsewhere.	Glazier (2009)
Crenoxenes	Species that occasionally occur in springs.	Glazier (2009)
Cryoconite	A mélange of sediments, wind-blown detritus, and even living and dead microscopic psychrophiles on a glacier's surface.	Takeuchi et al. (2015)
Cryoconite holes	Small, glacier-ice melt pools.	Wharton et al. (1985)
Cyanobacteria	Cyanobacteria are one of the largest and most important groups of bacteria on Earth. They live in water, and are photosynthetic. This means that they convert the carbon dioxide in the atmosphere into oxygen. Cyanobacteria are mainly responsible for generating the oxygen that is found in the Earth's atmosphere today. Although their common name is "blue-green algae," the cyanobacteria are bacteria, and are not related to algae.	GreenFacts Digests (2019)
Detritivore	Animals that feed primarily on fragments of organic matter (detritus) found in soil and bottom sediments.	Freshwater Information Platform (2019)
Detritus	Particulate organic matter.	Lincoln et al. (1998)
Dimictic	Lakes with a pattern of two mixing periods (spring turnover–summer stratification–fall turnover–winter stratification).	LakeAccess (2006)
Dissolved organic carbon	Dissolved organic carbon is generally defined as organic matter that is able to pass through a filter which removes material between 0.70 and 0.22 µm in size.	Strack et al. (2008)
Dissolved oxygen	Oxygen gas absorbed by and mixed into water.	Texas Aquatic Science (2013)
Domestic water use	Water used for household purposes, such as drinking, food preparation, bathing, washing clothes, dishes, and dogs, flushing toilets, and watering lawns and gardens.	United States Geological Survey (2019)
Drainage basin	The land area that contributes water to a stream or lake system or directly to the ocean; also referred to as a catchment basin.	Freshwater Information Platform (2019)
Drought	An extended period of below normal rainfall or other deficiency in water supply.	Texas Aquatic Science (2013)
Ecosystem services	Resources and processes that are supplied by ecosystems, generally grouped into four broad categories: provisioning, such as the production of food and water; regulating, such as the control of climate and disease; supporting, such as nutrient cycles and crop pollination; and cultural, such as spiritual and recreational benefits.	Texas Aquatic Science (2013)

<i>Term</i>	<i>Definition</i>	<i>References</i>
Ecotopes	The smallest ecologically distinct landscape features in a landscape mapping and classification system. As such, they represent relatively homogeneous, spatially explicit landscape functional units that are useful for stratifying landscapes into ecologically distinct features for the measurement and mapping of landscape structure, function and change.	Runhaar and Udo de Haes (1994)
Ectothermic	Having a body temperature determined primarily by the temperature of the environment (i.e., cold-blooded).	Lincoln et al. (1998)
Embodied water	Embodied (or virtual) water is a measure of the total water used in production of a good or service.	Hoekstra and Chapagain (2011)
Emergent plant	A plant rooted in shallow water with much of the stem and most of the leaves above water.	Freshwater Information Platform (2019)
Englacial	Interior of a glacier.	Hamilton et al. (2013)
Ephemeral streams	All flowing waters that cease flow and/or dry completely at some point along their course.	Datry et al. (2017)
Epilimnion	The uppermost and warmest layer (also called the mixed layer) of a lake that experiences density stratification induced by seasonal warming at the lake surface.	Lewis (2009)
Equilibrium line altitude	An upper elevation accumulation zone exists on glaciers, where snowfall exceeds melt; a low-elevation ablation zone exists, where melt exceeds snow accumulation. The equilibrium line altitude is the transition area between the two zones.	Dial and Ditto (2020)
Euphotic	That portion of a lake receiving sufficient solar irradiance to support photosynthesis (typically more than 1% of full solar irradiance).	Lewis (2009)
Eutrophic	Rich in basic nutrients.	Maitland and Morgan (1997)
Eutrophication	Enhanced primary productivity caused by nitrogen and phosphorous, organic pollution, intense catchment land use, and habitat degradation.	Freshwater Information Platform (2019)
Evaporation	The process of liquid water becoming water vapor, including vaporization from water surfaces, land surfaces, and snow fields, but not from leaf surfaces.	United States Geological Survey (2019)
Feed conversion efficiency	The efficiency with which the bodies of livestock convert animal feed into the desired output.	Fry et al. (2018)
Filter feeders	Any animal that feeds by filtering suspended particulate organic matter from water.	Lincoln et al. (1998)
Firn	An intermediate stage in the transformation of snow to glacier ice. Snow becomes firn when it has been compressed so that no pore space remains between flakes or crystals, a process that takes less than a year.	Molnia (2004)
Flood	An overflow of water onto lands that are used or usable by humans and not normally covered by water. Floods have two essential characteristics: the inundation of land is temporary; and the land is adjacent to and inundated by overflow from a river, stream, lake, or ocean.	United States Geological Survey (2019)
Floodplain	The land bordering a stream, built up of sediments from stream overflow and subject to inundation when the stream floods.	Freshwater Information Platform (2019)
Fluvial	Pertaining to rivers.	Freshwater Information Platform (2019)
Fluvial deposits	All sediments, past and present, deposited by flowing water.	Freshwater Information Platform (2019)
Freshwater fishes	Those that complete their entire life cycle in freshwater.	Polhemus and Richardson (2020)
Freshwater, fresh water	Water that contains less than 1000 mg per liter (mg/L) of dissolved solids; generally, more than 500 mg/L of dissolved solids is undesirable for drinking and many industrial uses.	United States Geological Survey (2019)
Glacier	A huge mass of ice, formed on land by the compaction and recrystallization of snow that moves very slowly downslope or outward due to its own weight.	United States Geological Survey (2019)
Gray water	Wastewater from clothes washing machines, showers, bathtubs, hand washing, lavatories and sinks.	United States Geological Survey (2019)
Green water	The precipitation on land that does not run off or recharge the groundwater but is stored in the soil or temporarily stays on top of the soil or vegetation.	Hoekstra et al. (2011)
Groundwater	Water in the zone of saturation where all open spaces in sediment and rock are completely filled with water.	Freshwater Information Platform (2019)
Groundwater recharge	Inflow of water to a groundwater reservoir from the surface. Infiltration of precipitation and its movement to the water table is one form of natural recharge. Also, the volume of water added by this process.	United States Geological Survey (2019)
Headwater streams	Headwater streams are the smaller tributaries that carry water from the upper reaches of the watershed to the main channel of the river.	Richardson (2019)
Helocrenes	A spring that results in a marshy bog.	Hynes (1970)
Helophyte	A perennial plant with renewal buds, commonly on rhizomes, buried in soil or mud below water level.	Lincoln et al. (1998)
Heterotrophic	Organisms that obtain nourishment from exogenous organic matter.	Lincoln et al. (1998)
Holomictic	Lakes having complete free circulation throughout the water column at the time of winter cooling.	Lincoln et al. (1998)
Homopycnal inflows	Incoming water and lake water of same density resulting in thorough mixing of the two.	Timms (2009)
Hydric soil	Soil that is wet long enough to periodically result in anaerobic conditions, influencing the growth of plants.	Cowardin et al. (1979)

(Continued)

<i>Term</i>	<i>Definition</i>	<i>References</i>
Hydrochory	Life history traits that depend on dispersal of seeds, fruits, and spores by water.	McManamay and Jager (2020)
Hydrogeology	The study of groundwater.	Mudd (2020)
Hydrogeomorphic	An interdisciplinary science that focuses on the interaction and linkage of hydrologic processes with landforms or earth materials and the interaction of geomorphic processes with surface and subsurface water in temporal and spatial dimensions.	Sidle and Onda (2004)
Hydrography	The study of investigating bodies of water.	Eckhardt (2019)
Hydrologic cycle	The cyclic transfer of water vapor from the Earth's surface via evapotranspiration into the atmosphere, from the atmosphere via precipitation back to earth, and through runoff into streams, rivers, and lakes, and ultimately into the oceans.	United States Geological Survey (2019)
Hydrology	The science of the properties, distribution, and effects of water.	Freshwater Information Platform (2019)
Hydroperiod	The duration of inundation by water over a year	Crane et al. (2013)
Hydrophyte	Plant growing in water or on substrate that is periodically deficient in oxygen resulting from excessive water content.	Cowardin et al. (1979)
Hydrophytic	Thriving in wet or aquatic situations.	Lincoln et al. (1998)
Hydropower	Electrical energy produced by falling water.	Eckhardt (2019)
Hydroregime	A system made up of water and the associated aquatic environments within a delimited geographical entity.	Greenberg et al. (2015)
Hyperpycnal inflows	Incoming water more dense than lake water, so it flows along the bottom of the lake.	Timms (2009)
Hypolimnetic	Cold bottom water below the thermocline in a lake.	Lincoln et al. (1998)
Hypolimnion	The most dense, deepest, and coolest layer of a thermally stratified lake. The hypolimnion does not support photosynthesis, because it lacks solar irradiance, and in many cases shows partial or complete depletion of dissolved oxygen.	Lewis (2009)
Hypopycnal inflows	Incoming water less dense than lake water, so it flows on the surface of the lake.	Timms (2009)
Hyporheic zone	Where groundwater intermixes with surface water.	McManamay and Jager (2020)
Hypoxia	A deficiency of oxygen; water having dissolved oxygen concentrations <2 mg/L.	Roman et al. (2019)
Industrial water use	Water used for industrial purposes in such industries as steel, chemical, paper, and petroleum refining.	United States Geological Survey (2019)
Infiltration	Flow of water from the land surface into the subsurface.	United States Geological Survey (2019)
Inselberg	Isolated rock outcrops that stand out abruptly from surrounding plains.	Potembski and Barthlott (2012)
Insulosity	The percentage of the lake area occupied by islands.	Lincoln et al. (1998)
Intermittent rivers	All flowing waters that cease flow and/or dry completely at some point along their course	Datry et al. (2017)
Interrupted streams	Streams which support perennial flow in their upper reaches, but become dry as this flow sinks into the bed further downstream, so that there is not continuous flow all the way to their mouth except during the wet season or after major rainstorms.	Polhemus et al. (1992)
Irrigation	The controlled application of water for agricultural purposes through constructed systems to supply water requirements not satisfied by rainfall.	United States Geological Survey (2019)
Irrigation water use	Water application on lands to assist in the growing of crops and pastures or to maintain vegetative growth in recreational lands, such as parks and golf courses.	United States Geological Survey (2019)
Jökulhlaup	A glacier outburst flood resulting from the failure of a glacier-ice-dam, glacier-sediment-dam, or from the melting of glacier ice by a volcanic eruption (Icelandic).	Molnia (2004)
Karst topography	A landscape typical of gypsum and limestone areas, where sinkholes have formed as a result of the dissolution of rocks by rainwater; narrow, crumbling ridges separate the sinkholes.	Freshwater Information Platform (2019)
Lacustrine deposits	Material deposited by or settled out of lake waters and exposed by the lowering of water levels or the elevation of land. These sediments range in texture from sand to clay and are usually varied (layered annual deposits).	Freshwater Information Platform (2019)
Lake	A large body of standing water.	Texas Aquatic Science (2013)
Lentic	Related to slow-moving water, such as in lakes and bogs.	Freshwater Information Platform (2019)
Limnetic	Pertaining to the open water of a lake away from the bottom.	Lincoln et al. (1998)
Limnetic zone	The part of a lake that is too deep to support rooted aquatic plants.	Texas Aquatic Science (2013)
Limnocrenes	A spring that results in a large, deep pool.	Hynes (1970)
Limnology	Scientific study of physical, chemical, and biological conditions in lakes, ponds, and streams.	Eckhardt (2019)
Limnophilous	Living in ponds or marshes.	Eckhardt (2019)
Lithophils	Aquatic species that protect eggs by depositing, burying, or hiding them within crevices of substrates.	McManamay and Jager (2020)
Littoral	Near the shore of a waterbody, where irradiance reaching the bottom is >1% of solar irradiance at the water surface.	Lewis (2009)
Littoral zone	The part of a lake that is shallow enough to support rooted aquatic plants.	Texas Aquatic Science (2013)
Livestock water use	Water used for livestock watering, feed lots, dairy operations, fish farming, and other on-farm needs.	United States Geological Survey (2019)

<i>Term</i>	<i>Definition</i>	<i>References</i>
Lotic	Related to fast-moving water, such as in most streams and rivers.	Freshwater Information Platform (2019)
Macrobenthos	Benthic animals large enough to be retained on a coarse (usually 0.5-mm mesh) sieve.	Strayer (2009)
Macrophyte	All aquatic higher plants, mosses and characean algae, but excluding single celled phytoplankton or diatoms.	Freshwater Information Platform (2019)
Marsh	A wetland dominated by reeds and other grass-like plants.	Texas Aquatic Science (2013)
Meander	A loop-like bend in a stream or river that develops when a watercourse flows through level land and erodes its floodplain.	Freshwater Information Platform (2019)
Meiobenthos	Benthic animals too small to be retained on a coarse (usually 0.5-mm mesh) sieve, but large enough to be retained on a fine (usually 0.05-mm mesh) sieve.	Strayer (2009)
Meromictic lakes	Lakes that are permanently stratified due to a density gradient resulting from chemical stratification.	Lincoln et al. (1998)
Metacommunity	A set of local communities connected by dispersal of organisms.	Leibold et al. (2004)
Metalimnion	A layer of transitional density and temperature that connects the epilimnion to the hypolimnion.	Lewis (2009)
Mining water use	Water use during quarrying rocks and extracting minerals from the land.	United States Geological Survey (2019)
Monomictic	Lakes and reservoirs that are relatively deep, do not freeze over during winter, and undergo a single stratification and mixing cycle during the year (usually in the fall).	Eckhardt (2019)
Moulin	A narrow, tubular chute or crevasse through which water enters a glacier from the surface.	Molnia (2004)
Mud	Loose slushy fine sediment consisting of clay, silt, fine sand, and organic material. Often water-formed and deposited on the bottom of lakes and rivers.	Freshwater Information Platform (2019)
Nekton	The assemblage of swimming organisms in a body of water.	Eckhardt (2019)
Nilotic	Relating to the Nile River or to the Nile region of Africa.	Bender (2019)
Nitrogen	An inorganic nutrient essential for plant growth and reproduction when in oxidized forms (nitrate, nitrite, ammonia); excess can cause eutrophication; problems are usually associated with agricultural runoff and sewage.	Chesapeake Bay Foundation (2019)
Non-point source	A pollution source that cannot be defined as originating from discrete points such as pipe discharge. Areas of fertilizer and pesticide applications, atmospheric deposition, manure, and natural inputs from plants and trees are types of non-point source pollution.	Freshwater Information Platform (2019)
Nye or N-channels	Channelized systems in glaciers that involve water flow through channels incised into the underlying bedrock or subglacial sediments.	DeBeer et al. (2020)
Oligomictic lakes	Lakes having a relatively stable stratification with only rare periods of circulation.	Lincoln et al. (1998)
Oligotrophic	Having a low supply of plant nutrients.	Eckhardt (2019)
Organic matter	Plant and animal residues, or substances made by living organisms. All are based upon carbon compounds.	United States Geological Survey (2019)
Orographic rainfall	Rainfall produced by supersaturation of an air mass forced upward by a mountain range.	Lincoln et al. (1998)
Oxbow lake	A lake formed when river meanders are cut off from the main channel.	Freshwater Information Platform (2019)
Psychrophiles	Literally meaning cold-loving; these are organisms adapted to growth at low temperatures, having an optimum growth temperature of <15 °C and a maximum growth temperature of <20 °C.	Scherer and Neuhaus (2006)
Peak glacier water	Annual runoff of water from glaciers continues to rise until a maximum ("peak water") is reached, beyond which runoff steadily declines.	Huss and Hock (2018)
Pelagic	Living and feeding in the water column, as opposed to living associated with a sea or lake bottom, see also benthic.	Freshwater Information Platform (2019)
Percolation	The movement of water through the subsurface soil layers, usually continuing downward to the groundwater or water table reservoirs.	Eckhardt (2019)
Perennial streams	Streams which maintain flow throughout their entire length and discharge continuously to their mouth during all seasons, irrespective of seasonal variations in precipitation.	Polhemus et al. (1992)
Phosphorous	An inorganic nutrient essential for plant growth and reproduction; excess can cause eutrophication; problems are usually associated with farmland runoff, sewage, and detergents.	Chesapeake Bay Foundation (2019)
Phreatic water	Permanent groundwater that has very slow flow rates and consequently longer residence times—decades or even centuries.	Culver and Pipan (2013)
Phytolithophils	Aquatic species that protect eggs by depositing them on plants.	McManamay and Jager (2020)
Phytoplankton	Microscopic plants that float or drift almost passively in oceans, lakes, or rivers.	Freshwater Information Platform (2019)
Phytotelmata	Small pools of water within or upon plants.	Lincoln et al. (1998)
Phytotelmic	Organisms that inhabit small pools of water within or upon plants.	Lincoln et al. (1998)
Planktivores	Organisms that feed on planktonic organisms.	Lincoln et al. (1998)
Plankton	Microscopic free-floating living organisms not attached to the bottom or able to swim effectively against most currents.	Texas Aquatic Science (2013)

(Continued)

<i>Term</i>	<i>Definition</i>	<i>References</i>
Point source	A source at a discrete location such as a discharge pipe, drainage ditches, well, or concentrated livestock operation. Point source pollution arises from a discrete source, e.g., the discharge from a sewage treatment works. See also non-point source.	Freshwater Information Platform (2019)
Pollutant	A substance that contaminates the water, air, or soil.	Texas Aquatic Science (2013)
Polymictic lakes	Lakes without a persistent thermal stratification and which circulate continuously with brief periods of stability.	Lincoln et al. (1998)
Pond	A body of standing water small enough that sunlight can reach the bottom across the entire diameter.	Texas Aquatic Science (2013)
Pondscape	A network of ponds with ecological interactions.	Lemmens and Pinceel (2020)
Pool	Part of a stream where the water slows down, often with water deeper than the surrounding areas, which is usable by fish for resting and cover.	Texas Aquatic Science (2013)
Pool/riffle ratio	The ratio of surface area or length of pools to the surface area or length of riffles in a given stream reach; frequently expressed as a relative percentage of each category. Used to describe fish habitat rearing quality.	Texas Parks and Wildlife Department (2019)
Potable	Water suitable, safe, or prepared for drinking.	Eckhardt (2019)
Potamodromous	Within river migration.	Lucas and Baras (2008)
Precipitation	Rain, snow, hail, sleet, dew, and frost.	United States Geological Survey (2019)
Primary consumer	Organisms that consume primary producers.	Chaloner et al. (2009)
Primary producer	Organisms that generate organic compounds from inorganic nutrients.	Chaloner et al. (2009)
Profundal zone	A lake's deep-water region that is not penetrated by sunlight.	Eckhardt (2019)
Psychrophilic	Cold-loving life (usually microbial).	Dial and Ditto (2020)
Rain	Water drops which fall to the Earth from the air.	Eckhardt (2019)
Reach	In general, a length of stream with relatively homogenous characteristics.	Eckhardt (2019)
Recharge	Water added to an aquifer. For instance, rainfall that seeps into the ground.	United States Geological Survey (2019)
Reoligotrophication	Lakes and similar water bodies that are poor in nutrients and plant life and rich in oxygen.	Gerdeaux (2004)
Resilience	The capacity to recover from disturbance.	Datry et al. (2014)
Resistance	The capacity of a species, a community, or an ecosystem to persist unchanged by and during a disturbance.	Stanley et al. (1994)
Restoration	The return of an ecosystem to a close approximation of its condition prior to disturbance.	Texas Parks and Wildlife Department (2019)
Return flow	Surface water that returns to the natural environment after diversion for beneficial uses, such as for irrigation.	Eckhardt (2019)
Rheocrenes	Flowing springs, often emerging from and passing over bedrock faces.	Hynes (1970)
Riffle	A shallow section in a river or stream where the water flows swiftly; may be less turbulent than rapids.	Freshwater Information Platform (2019)
Riffle-pool section	Regular alternation of shallow (riffle) areas with higher current velocities and gravel-cobble substrates followed by deeper slow-flowing pool areas with finer substrates. Mountain streams often have a fixed riffle-pool sequence.	Freshwater Information Platform (2019)
Riparian (area)	The area adjacent to a stream or river with a high density, diversity, and productivity of plant and animal species relative to nearby uplands.	Freshwater Information Platform (2019)
River	A natural stream of water of considerable volume, larger than a brook or creek.	United States Geological Survey (2019)
River basin	The whole river system including all tributaries and springs from the source to the mouth (sea).	Freshwater Information Platform (2019)
Riverine	Relating to, formed by, or resembling a river including tributaries, streams, and brooks.	Texas Parks and Wildlife Department (2019)
Röthlisberger or R-channels	Channelized systems in glaciers that involve water flow through ice-walled conduits that are kept open where the rate of wall melting exceeds the rate of conduit closure due to ice creep.	DeBeer et al. (2020)
Runoff	The part of rain and snowmelt that runs over the ground and into a stream or other water body.	Freshwater Information Platform (2019)
Scour(ing)	Removal of sediment from the streambed by flowing water.	Freshwater Information Platform (2019)
Sediment	Soil particles, sand, and minerals washed from the land into aquatic systems as a result of natural and human activities.	Eckhardt (2019)
Seep	A spot where water contained in the ground oozes slowly to the surface and often forms a pool; a small spring.	Eckhardt (2019)
Sewage	The waste and wastewater produced by residential and commercial sources and discharged into sewers.	Eckhardt (2019)

<i>Term</i>	<i>Definition</i>	<i>References</i>
Shredders	Organisms that feed off of coarse particulate organic material such as small sections of leaves. They ingest the organic matter along with volunteer organisms (fungi, microorganisms) attached to the source.	Benfield and Webster (1985)
Siltation	The deposition of finely divided soil and rock particles upon the bottom of stream and river beds and reservoirs.	Eckhardt (2019)
Snow	Precipitation in the form of branched hexagonal crystals often mixed with simple ice crystals, which fall more or less continuously from a solid cloud sheet. These crystals may fall either separately or in cohesive clusters forming snowflakes.	Eckhardt (2019)
Spring	A defined area where a natural discharge of groundwater returns to the surface.	van Everdingen (1991) and White (2019)
Stagnicolous	Living in stagnant water.	Eckhardt (2019)
Step-pool	A step-pool system is a geomorphologic phenomenon occurring in high-gradient mountain streams >3% with alternating steps and pools having a stair like appearance.	Chin (1999)
Stream	A general term for a body of flowing water; natural water course containing water at least part of the year. In hydrology, it is generally applied to the water flowing in a natural channel as distinct from a canal.	United States Geological Survey (2019)
Stream bed	The stream bottom.	Freshwater Information Platform (2019)
Stream order	A hydrologic system of stream classification. Each small unbranched tributary is a first-order stream. Two first-order streams join to make a second-order stream. A third-order stream has only first and second-order tributaries, and so forth.	Texas Parks and Wildlife Department (2019)
Stream reach	An individual segment of stream that has beginning and ending points defined by identifiable features such as where a tributary confluence changes the channel character or order.	Texas Parks and Wildlife Department (2019)
Stygobites	Stygobites are obligate inhabitants of groundwater systems.	Humphreys (2006)
Subglacial	Area between glacial ice and basal bedrock.	Hamilton et al. (2013)
Sublimation	The transition of water directly from the solid state to the gaseous state, without passing through the liquid state; or vice versa.	Eckhardt (2019)
Subsidence	Sinking down of part of the earth's crust due to underground excavation, such as removal of groundwater.	Eckhardt (2019)
Supraglacial	Surface of a glacier.	Hamilton et al. (2013)
Surface water	All moving and standing water naturally open to the atmosphere.	Freshwater Information Platform (2019)
Suspended solids	The small solid particles in water that cause turbidity. Particles of suspended sediment tend to settle at the channel bottom, but upward currents in turbulent flow counteract gravitational settling.	Eckhardt (2019)
Swamp	A wetland in which trees or woody shrubs predominate.	Texas Aquatic Science (2013)
Thermocline	Fairly thin zone in a lake that separates an upper warmer zone (epilimnion) from a lower colder zone (hypolimnion).	Eckhardt (2019)
Thermokarst	A land surface characterized by very irregular surfaces of marshy hollows and small hummocks formed as ice-rich permafrost thaws; it commonly occurs in Arctic areas, and on a smaller scale in mountainous areas.	Pollard (2018)
Transpiration	Process by which water that is absorbed by plants, usually through the roots, is evaporated into the atmosphere from the plant surface, such as leaf pores.	United States Geological Survey (2019)
Tributary	A stream that feeds into a larger stream. Also called a feeder stream.	Freshwater Information Platform (2019)
Vadose	Water in the Earth's crust above the level of permanent ground water.	Lincoln et al. (1998)
Virtual water	Virtual (or embodied) water is a measure of the total water used in production of a good or service.	Hoekstra and Chapagain (2011)
Water quality	A term used to describe the chemical, physical, and biological characteristics of water, usually in respect to its suitability for a particular purpose.	United States Geological Survey (2019)
Water table	Level below the earth's surface at which the ground becomes saturated with water. The surface of an unconfined aquifer which fluctuates due to seasonal precipitation.	Eckhardt (2019)
Water year	A continuous 12-month period for which hydrologic records are compiled and summarized.	Texas Parks and Wildlife Department (2019)
Waterfall	A cascading feature with a gradient of 40% or greater.	Polhemus and Richardson (2020)
Watershed	A planning term that refers to the area from which surface water drains into a common lake or river system or directly into the ocean; also referred to as a drainage basin or catchment basin.	Freshwater Information Platform (2019)
Wetland	Wetlands are lands that are permanently or periodically saturated with water, which impacts the nature of soil development and what animals and plant communities live in the soil and on its surface.	Cowardin et al. (1979)
Zoobenthos	The community of animals living around surfaces (e.g., sediments, plants) in aquatic ecosystems.	Strayer (2009)

Glossary

Abiotic Without life.

Abyss The great depths of the oceans, usually considered to be depths of 2000–6000 m, a region of low temperatures, high pressure, and an absence of sunlight.

Abyssal hills Tract, sometimes extensive, of low (100–500 m) elevations on the deep sea floor.

Abyssal plain An extensive, flat, gently sloping or nearly level region at abyssal depths.

Abyssopelagic Open water habitat of the abyss. Distinct from the benthic (seabed) habitat.

Accretion Process of sediment build-up.

Acoustic backscatter A method of detecting discontinuities in the water, often used for current and turbidity measurements and for detecting changes in the character of the seafloor.

Adaptation A process by which species evolve, and by which individuals adapt, their growth and/or behavior to better survive and grow in a particular environment.

Adaptive radiation Process of new species evolving to adapt to different environmental conditions.

Advection The horizontal movement of water, or a property of water through such movement (e.g., temperature change through the movement of water).

Aggradation Reworking of the sediment by waves and currents.

Aggregate The collective term for sand, gravel and crushed rock typically used by the building industry. They can be compacted to firmly fill a space and are often bound together with cement (to make concrete) or bitumen (for road surfacing).

Aggregation A collection of animals or plants gathered or clustered together.

Algae The simplest plants; maybe single-celled (such as diatoms) or quite large (such as seaweeds). Live in salt or fresh water and on land.

Allopatric speciation The process through which species arise while separated geographically.

Alpha-diversity The number of species in a sample.

Aphotic zone The part of the water column where light does not penetrate.

Apron Gently dipping seabed surface comprised of sediment found at the base of a slope; commonly the product of slumping (sediment failure) of a steep slope.

Archaeology The study of historic and prehistoric communities.

Archipelago A group of adjacent islands.

Assemblage A neutral substitute for “community” but implying no necessary interrelationships among species; also called species assemblage.

Atoll An annular reef enclosing a lagoon in which there are no promontories other than reefs and islets composed of reef material.

Bank Elevation of the seabed over which the depth of water is relatively shallow. Sand banks are sedimentary features longitudinal to the current.

Barrier Islands Elongate offshore islands or sandbanks oriented parallel to the coastline which may form a lagoon between the island and the coast and which protect the coast from prevailing wave action.

Basin Depression, characteristically in the deep sea floor, more or less equidimensional in shape and of variable extent.

Bathyal Deep-sea, variously attributed to range from 200 to 2000 m or 4000 m depth.

Bathymetry Seafloor elevations and the variations in water depth; the topography of the seafloor.

Bathypelagic The zone of open water below the euphotic (well-lit) and mesopelagic (poorly lit) but above the abyssopelagic.

Bay, embayment A body of water partly enclosed by land.

Beach draw down Removal of sediment deposits from a beach by waves and currents.

Beach recharge Placement of aggregates on beaches to replace that lost by erosion (beach nourishment) or to protect coastal resources.

- Bedform** Sedimentary features of the seabed oriented transverse to flow direction; ripples, dunes, and sand waves.
- Bedload transport** The transport of sediments by currents, rolling or hopping along the seabed.
- Bejerrnick's Law** "Everything is everywhere, the environment selects." This means that species have the potential to be everywhere over time but that the environment selects which species live in a place. While strictly untrue, there is evidence that it applies relatively more to microscopic than larger organisms.
- Benthic boundary layer** A zone of the water column close to the seabed within which sediment (bedload) transport occurs.
- Benthic ecology** The nature and distribution of organisms on or within the seabed and the interactions between them and their environment.
- Benthic fauna** Animals that live on or within the seabed.
- Benthic** Associated with the seafloor.
- Benthos** The collection of organisms living on or within the seabed.
- Berm** A narrow shelf, bank, or ledge at the top or bottom of a slope; in coastal geomorphology a sedimentary feature (ridge) built along the coast, above the level of high tide, by storm wave action.
- Beta-diversity** The turnover of species composition between samples in a geographic area.
- Biocoenosis** The "living community"; formulated in 1877 by Karl Möbius; describes the organisms living in the same habitat, and is a now used synonymously with the term "community."
- Biodiversity** The Convention of Biological Diversity definition encompasses the variation within species (genetic, phenotypic), between species, and of ecosystems (habitats, productivity, processes). Most commonly used to describe variation between species.
- Biogenic habitat** Physical habitat created by living organisms, such as coral reefs, oyster beds, tubeworm reefs, kelp beds, seagrass beds.
- Biogeographic boundary** The area across which species composition changes more rapidly than within a biogeographic region. Not to be confused with habitat boundaries and ecotones.
- Bioherm** Mound-shaped deposits of rock and sediment produced by marine organisms. Coral reefs and *Halimeda* banks are well-known examples.
- Biomass** The mass of organisms in a sample measured as weight.
- Biome** A large geographic area dominated by a plant life-form that provides physical habitat for other species. Used on land for deciduous forests, tundra, grasslands. Comparable marine biomes are seagrass beds, kelp and mangrove forests, and coral reefs with symbiotic algae.
- Bioregionalisation** A spatial representation depicting the boundaries of hierarchical geographic areas considered useful for environmental management.
- Biota** All living organisms, including fauna and flora, within a defined area.
- Biotone** A zone of transition between core provinces used in an Australian bioregionalisation scheme. Biotones are not simply "fuzzy" boundaries but represent unique transition zones between the core provinces.
- Biotope** A habitat with a characteristic community. Also called facies.
- Boulder** Sediment grains >256 mm diameter.
- Boundary-layer currents** Currents at the sediment-water interface.
- Brackish** Neither freshwater nor full-salinity seawater. Typically with 1–20 ppt salinity. See "Estuarine."
- Burrowing** Organisms that burrow in the substratum, be it sediments or rocks.
- Canyon** A relatively narrow, deep depression with steep sides, the bottom of which generally has a continuous slope, developed characteristically on some continental slopes.
- Cay** A small, low elevation sandy island formed on the surface of a coral reef.
- Channel** A narrow sea area, often with strong currents, between island and mainland, between two major islands, or created by currents in seafloor sediment (e.g., deep-sea channel).
- Chemoautotroph** Organisms that create energy from chemical reactions, as distinct from phototrophs which use sunlight.
- Circalittoral** Seabed on the Continental Shelf dominated by animals, where benthic algae are rare or absent. It is usually seasonally stratified, and the effect of wave action is limited to storms. Typically considered between 50 and 200 m depth range.
- Clay** Particles of between 0.00024 and 0.0039 mm in size, or all particles <0.004 mm in diameter. Smaller than silt. In contrast to silt, clay has colloidal properties (i.e., particles unlikely to settle when floating in a liquid). Mud is comprised of clay and silt.
- Cline** A geographic gradient in some variable, such as a species attribute (e.g., color).
- Cobble** Sediment grains 64–256 mm in diameter.
- Cold seep** Area of seafloor where gases and fluids are released but not hot water (hydrothermal vent).
- Colonial** Animals that live as a part of one physically connected colony, such as corals, bryozoans and some tubeworms and tunicates.
- Colonization** Process of organisms establishing themselves in an environment where they were not already present.

Commensal Organisms of different species that live together, sharing space or food, whereby at least one partner benefits from the association and neither have detrimental effects on the other (i.e., not parasitic).

Community A group of species that are assumed to be interdependent (though this is often not demonstrated). The term can be used in a variety of hierarchies. Communities at larger scales can be progressively subdivided, such as spatially, taxonomically and trophically, to finer scales.

Competitive exclusion One species excludes another due to being a superior competitor for a resource.

Competitive release The absence of a competitor allows a species to increase in abundance and/or distribution.

Continental margin The submerged prolongation of continental landmass consisting of the seabed and subsoil of the continental shelf, slope and rise but not the deep ocean floor.

Continental rise A gentle slope rising from the oceanic depths toward the foot of a continental slope of between 1 and 2 degrees slope.

Continental shelf Seafloor that is the submerged part of a continent, extending from the low water line to a depth at which there is usually a marked increase of slope toward oceanic depths; often generalized to about 200 m depth.

Continental slope Surface dipping seaward from the continental shelf edge typically with a slope of >2 degrees and extending to the upper limit of the continental rise, or the point where there is a general decrease in steepness.

Convection The vertical movement of water as part of its stirring caused by differences in density.

Coral reef platform The flat or nearly flat area of considerable extent, dropping off abruptly on one or more sides, extending around a coral reef in the photic sea surface waters and composed of live and/or dead coral reef.

Coral reef (see also "Reef") Reefs developed through biotic processes dominated by corals. In geology, sedimentary features, comprised of macroscopic skeletal framework, built by the interaction of organisms and their environment, that have synoptic relief and whose biotic composition differs from that found on and beneath the surrounding sea floor.

Corridor Narrow geographic areas considered to facilitate the dispersal of species from one area to another across an otherwise unsuitable environment.

Deep In oceanography, an obsolete term which was generally restricted to depths greater than 6000 m.

Delta Seaward prograding sediment body deposited at the mouth of a river.

Demersal A species living on or near the seabed. Commonly used for near-seabed living fish.

Deposit feeding Animals that feed on sediments and other material deposited on the seabed.

Digital terrain model (DTM) Also digital elevation model (DEM). A three-dimensional grid representation of the shape of the earth (seafloor or land) surface.

Diversity Biological or ecological diversity is most commonly measured as the number of species, also called species richness. Many other indices of diversity include the relative abundance of species as well as species richness in their calculation. These indices may emphasize the dominance or evenness of the abundance of species in a sample. See Alpha, beta, gamma diversity, and biodiversity.

Dominant species A species that dominates a sample or area by virtue of its abundance, biomass, size, or conspicuousness.

Downwelling The process by which surface waters sink to greater depths in the ocean. Important mechanisms are cooling of surface waters and/or addition of salt through the production of sea ice in polar seas.

Dune Sedimentary bedforms larger than ripples, greater than 0.6 m in wavelength and greater than around 10 cm in height. Dunes are mostly asymmetrical in profile, with a gentle upcurrent stoss slope and a steeper down-current lee slope which may be at the angle of repose of the sediment. Dune crestlines may be either linear (two-dimensional) or nonlinear (three-dimensional, barchan-shape) in plain view. Large dunes may have smaller dunes superimposed upon them (see also "Sand waves").

Dysphotic zone The part of the water column, below the euphotic zone, that receives low levels of sunlight but insufficient to support plant growth; see also "Mesopelagic."

Ecosystem The combination of species, their interactions, and the physical and chemical processes in their environment in a defined area.

Ecotone A transition zone between two ecologically distinct areas such as habitats, biotopes or ecosystems.

Encrusting Form of growth of animals and plants with a tough or hard texture (the crust), over rocks, and other materials.

Endemic Species only known to occur at one location or area of defined extent, such as a country or sea area.

Epibenthos The collection of organisms living upon the seabed, including animals (epifauna) and plants (epiflora) living on the surface of the seabed or on other animals and plants that live there.

Epibiota Animals, plants and microbes living on the seabed.

Epipelagic The collection of organisms living in well-lit (euphotic) surface waters of the open ocean; above the mesopelagic.

Errant Animals that can wander, are mobile. As distinct from sessile and sedentary.

Escarpment Elongated and comparatively steep (sometimes vertical) slope separating flat or gently sloping areas at different average depth.

Estuary The seaward portion of a drowned valley system which receives sediment and water from both fluvial and marine sources giving rise to a unique sedimentary regime and areas of variable salinity.

- Eulittoral** The area between the low and high tide marks, and the supralittoral and sublittoral fringe. Also called mediolittoral, tidal flat, and hydrolittoral.
- Euphotic zone** The upper part of the water column that receives sufficient light to allow plant growth.
- Euryhaline** Organisms that can live in a wide range of salinities.
- Eutrophication** The environmental problem of excessive plant growth (e.g., Planktonic or benthic alga) leading to oxygen fluctuations (hypoxia, anoxia, and supersaturation), and where dead and rotting plants create a public nuisance. Typically results from the release of nutrients from human activities.
- Evenness** Also called equitability, refers to how the abundance of species is distributed in a sample or group of samples. If all species have equal abundance then evenness is maximized. The inverse of evenness is dominance.
- Extinction** The disappearance of a species from Earth.
- Extirpation** The disappearance of a species from a defined geographic area.
- Fan** Relatively smooth, fan-like, depositional feature normally sloping away from the outer termination of a canyon or canyon system.
- Fauna** Animals; covering both invertebrates and vertebrates.
- Fetch** The unobstructed distance of ocean over which wind has blown to create observed surface waves.
- Fines** Small particles such as sand and silt.
- Fjord** A long, narrow, deep inlet of the sea between steep slopes, formed by glacial erosion. Sometimes spelt "fiord."
- Floodplain** A strip of relatively flat and normally dry land alongside a stream, river, or lake that is covered by water during a flood.
- Food web** A term used to describe the food relationships between members of a community.
- Founder effects** The consequence of founding parents genes for their progeny. With only a few founders, the species may be considered to have gone through a genetic "bottleneck."
- Fragmentation** The breakup of an area of habitat such that what was one population of a species is now several disconnected populations which may consequently be at greater risk of extirpation.
- Frequency range (Hz)** The wavelength of sound measured in cycles (wavelengths) per second; one Hertz (Hz) is a sound wave that travels at one cycle per second.
- Front** In oceanography, a vertical hydrographic boundary between two water masses which are distinguished by their temperature, salinity, and/or productivity.
- Gamma-diversity** The total number of species in a large geographic area. See Alpha- and beta-diversity.
- Gene flow** Exchange of genes within a population or between populations that reduces genetic diversity.
- Genetic drift** Accumulation of random mutations of alleles over time with a consequent change in genetic make-up.
- Geodiversity** The natural range (diversity) of geological (rocks, minerals, and fossils), geomorphological (landforms and processes), and soil (sediment) features. It includes their assemblages, relationships, properties, interpretations, and systems.
- Geophysical anomaly** An abrupt change in the geophysical features of the seabed, potentially associated with wrecks and archaeological sites.
- Geophysics** The study of the physics of the earth. Geophysical survey techniques use physical properties themselves (e.g., magnetism) or apply properties to see how the earth affects them (e.g., radar), to determine something about the earth's structure.
- Glacial outwash** Deposits of material washed out from glaciers by rivers.
- Glaciation** The formation, movement, and recession of glaciers.
- Granulometry** Determination of particle size composition of sediments.
- Gravel** Sediment grains 2–4 mm in diameter.
- Gregarious** The behavior of animals that live in groups, but can survive singly.
- Groynes** Breakwaters used to reduce the rate of transport of beach deposits.
- Guild** An association or classification for a group of species, often not taxonomically related, that share or use a resource in a similar way (e.g., sediment living macrofauna, gelatinous zooplankton), or live in the same part of the environment (e.g., plankton, benthos).
- Gullies** Narrow channels of one to tens of meters in width, created by moving water.
- Guyot** Seamount having a comparatively smooth flat top formed by wave erosion, coral reef growth, or aerial erosion and subsequent subsidence below the sea level.
- Habitat** The environment where an individual, species or group of species live that can be repeatedly found in nature.
- Hadal** Pertaining to depths of the ocean greater than 6000 m.
- Hadopelagic** Open water habitat of the hadal region. Below the abyssal.
- Harbor** Inlet with a port facility.
- Haul-out site** A site where seals come onto the shore or sandbanks.
- Hole** Local circular depression, often steep-sided, of the seafloor.
- Holocene** Epoch of geologic time spanning the last 11,700 years from the end of the Pleistocene Epoch (and the end of the last ice age) to the present.
- Hydrocarbon seep** Feature of the seafloor where hydrocarbons are being released through the seabed sediments.

Hydrodynamic processes Processes associated with waves, tides, and currents.

Hydrothermal vent A hot water spring on the ocean floor.

Hyperbenthos Animals that live close to the seabed but are not usually on it (i.e., epibenthos, epifauna) or in it (i.e., endobenthos, infauna). Typically used for crustaceans but in theory could include other taxa. The term demersal is used for fish.

Immigration The arrival of organisms to a place, which may result in their establishment (colonization).

Infauna Animals living within sediments.

Infralittoral Always submerged, below the low-tide within the euphotic zone. Seabed often dominated by algae, with variable water column temperatures.

Inlet Semi-enclosed area of the coast. Related terms include sea lough (Ireland), sealoch (Scotland), fjord, fiard, ria, voe.

Inquiline Animals that live within other organisms but are not considered parasitic. Similar to commensal ("living with") but usually used where the relationship has yet to be determined.

Inshore Generally within 5 km of the coastline and <50 m depth. Same as coastal seas. In the United Kingdom, the term "Inshore" applies specifically to the area within 6 nm of the coast where marine activities are managed at a local or regional scale.

Interstitial Organisms living in the space between grains of sediments. See also "Meiofauna."

Intertidal zone The area between the high-water mark and low-water mark that is submerged at high tide and exposed at low tide. Often used synonymously with seashore.

Island Land surrounded by water.

Island biogeographic theory Holds that the number of species in a location is a result of the interaction between the number colonizing and going extinct, such that islands that are larger and near a mainland source for colonist will have more species than smaller and more remote or isolated islands. This balance between colonization and extinction is also termed "Species equilibrium theory."

Knoll Relatively small (500–1000 m tall) isolated elevation of a rounded shape; a small seamount. Larger than a sea-hill.

Knot A speed of one nautical mile (nm) per hour.

Lagoon A shallow marine (sometimes brackish to hypersaline) coastal water body, receiving little—if any—fluvial input, separated from the sea by a restricted inlet usually having a sill.

Landform Geomorphological feature.

Latitudinal gradients Changes in the number (richness) of species with latitude.

Littoral drift The net movement of material along the shore under the influence of prevailing waves and currents.

Littoral Between upper and lower tidemarks, exposed to air at the lowest tides. In marine ecology is equivalent to intertidal and seashore. In wider literature may refer to coastal land and subtidal areas down to 200 m.

Macro-ecology Ecological patterns across geographic areas.

Macrofauna Fauna typically retained on a 1 mm sieve, visible but not usually identifiable to species level by eye.

Magnetometer Also known as a fluxgate gradiometer. A remote sensing instrument capable of identifying subsurface archaeological features by measuring the difference in their magnetic properties against the surrounding soils.

Managed retreat Areas where the sea is allowed to inundate sites formerly protected by sea defenses.

Marine protected area (MPA) Defined by the IUCN as "any area of intertidal or subtidal terrain, together with its overlying water and associated flora, fauna, historical and cultural features, which has been reserved by law or other effective means to protect part or all of the enclosed environment." See IUCN for updates.

Megafauna Large animals easily identified by eye without magnification; e.g., Mammals, birds, fish, sharks, turtles, lobsters, starfish. Larger than macrofauna.

Meiofauna Fauna retained on a 0.1 mm sieve but that pass through a 1 mm sieve. Smaller than macrofauna.

Mesolithic Middle stone age period ("middle stone age").

Mesopelagic Referring to the poorly lit open water habitat below the epipelagic (euphotic) and above the bathypelagic. Also called the twilight zone.

Metapopulation A population that exists in a connected complex of spatially discrete populations, such as in habitat fragments.

Microfauna Bacteria and small unicellular organisms not visible to the naked eye or retained on standard sieves.

Mid-domain effect The proposition that the environment constrains species ranges such that more ranges will overlap in the tropics, and thus more species will occur there.

Mitigation Measures to minimize, reduce or eliminate impacts.

Mud Sediment grains <0.063 mm diameter. Includes silt and clay.

Multibeam data Bathymetric and backscattered data derived from multibeam echo sounder.

Narrows Narrow channels of water forming the entrance to inlets, often with shallow sills and called Rapids.

Neap tide The minimum amplitude of the astronomical tide (every 14 days between the full and new moon).

Nekton An aquatic organism, such as whales, turtles, fish, squid, and krill (euphausiids) that can swim powerfully enough to move against currents.

Neolithic Later stone age period ("new stone age").

Neritic Pertaining to the water column overlying the continental shelf.

Net transport The residual movement of sediment after its oscillatory movement on tidal currents, or under the influence of waves.

Neuston The collection of organisms living on the sea surface (epineuston) or within the top 20 cm of the surface (hyponeuston).

Niche The range of environmental conditions (such as temperature, salinity, nutrients) within which a species can exist and reproduce. Sometimes defined as everything a species is or does. The preferred (or fundamental) niche is the one in which the species performs best in the absence of competition or interference from extraneous factors.

Noise Defined as unwanted sound and is usually measured in decibels (dB) referenced to an acoustic source frequency dB(A).

Nursery ground An area of importance for juvenile animals and plants.

Oceanic Referring to the open ocean, away from coastal waters.

Offshore Open ocean distant from land, typically with stable water column characteristics (stenothermal, stenohaline), permanently stratified, beyond freshwater influence, without benthic algae. Generally >5 km from the coastline.

Omnivore An animal that eats both animal and plant food.

Open coast Any part of coast not an island or inlet.

Overburden Sediment (often sand) deposited on top of local sediments OR deposits of soil and rock that are removed to gain access to ore deposits at open cast mines.

Overfalls Areas of rough water (relatively higher surface waves) generated by sudden changes in seabed topography, such as sandbanks and deeps.

Oxygen minimum zone Area of the ocean with seasonal or permanently low oxygen conditions.

Palaeolithic Earlier stone age period ("old stone age").

Palimpsest Sediment that exhibits attributes of a previous depositional environment, but also attributes of the modern environment.

Parasitic Organisms that feed on a host but do not normally lead to its death.

Parthenogenic Female animals that can produce fertile eggs without fertilization from sperm.

Pebble Sediment grains 4–64 mm diameter based on the Cailleux and Wentworth classification.

Pelagic Organisms, relating to or living in the water column of seas and oceans (as distinct from benthic). Includes nekton and plankton.

Phanerogam meadow Extended or patchy areas of seagrass in the Mediterranean Sea colonized by *Posidonia oceanica* (L.), and/or *Cymodocea nodosa* (Ucria). In other areas formed by the seagrasses *Posidonia*, *Zostera*, or related species.

Phototrophic Organisms (chemoautotrophs) that generate energy using sunlight. See "Chemoautotroph."

Physiognomy The apparent characteristics, outward features, or appearance of ecological communities often characterized by dominant species.

Physiography The physical geography of the land and seabed. See "Terrain," "Topography."

Phytoplankton Microscopic free-floating plants that drift in sunlit surface waters.

Pinnacle High tower or spire-shaped pillar of rock or coral, alone or cresting a summit. It may extend above the surface of the water. It may or may not be a hazard to surface navigation.

Plankton The collection of organisms, often microscopic, that are suspended freely in the water column.

Plateau Flat or nearly flat area of considerable extent, dropping off abruptly on one or more sides.

Pleistocene Epoch of geologic time during the Quaternary period extending from the end of Pliocene epoch around 2.6 million years ago up to the beginning of the Holocene epoch, 11,700 years ago.

Pleuston The collection of organisms that live on the ocean surface.

Pockmarks Small (1–10's m) circular depressions in the seafloor caused by the release of a gas or liquid (e.g., hydrocarbon seeps).

Polynya From the Russian word for "lake," an area of open water surrounded by sea ice.

Primary production Production of organic matter by converting light or chemical energy from primary materials, such as photosynthesis and chemosynthesis.

Progradation Reworking of the sediment by waves and currents toward deeper ocean due to sea level fall.

Quaternary Period of geologic time extending from the end of Pliocene epoch around 2.6 million years ago up to the present; a collective term for the Holocene and Pleistocene epochs.

Rapoport's rule The proposition that species geographic ranges increase with latitude and elevation (and perhaps depth), and thus there are more species in the tropics.

Realm A biogeographic region defined by an assemblage of species distinct from other regions, with characteristic endemic (geographically rare or localized) species. Distinct from habitat which is characterized by its dominant species (often common species), and biome (see above).

Recolonization The reestablishment of marine populations in an area from which they had been lost.

Recruitment The influx of new members into a population by either reproduction or immigration.

Reef ridge Long, narrow elevation with steep sides composed of live or dead coral.

Reef(s) Hard substrata raised from the seabed that provide a substratum and/or cover for marine life. May be formed by rocks, coral, shells, tube-worms, and other organisms. Also, used in hydrography to refer to hard substrata that may be a hazard to safe navigation.

Relaxation effect The consequence of habitat fragmentation that splits populations such that some are extirpated, and thus the species richness declines following fragmentation. Island Biogeographic Theory predicts a loss of species richness due to a decreased habitat area.

Relaxation time The time required for species and populations to adjust to changed environmental conditions.

Relict Sediments that were originally deposited under different environmental conditions than those occurring today. See also "palimpsest." The term is also used for relict populations of a species "trapped" in an environment that is a refuge of former more widespread environmental conditions that allowed the species a wider distribution range.

Relief The variation in the elevation (or depth) of the seafloor.

Ridge (A) Long, narrow elevation with steep sides. (B) Long, narrow elevation often separating ocean basins. (C) Linked major mid-oceanic mountain systems of global extent.

Ripple Sedimentary bedforms smaller than dunes (see "Dune").

Rock Ecologically is a "hard substratum" with an epibiota but where infauna is absent or rare.

Rough ground Areas of seabed where there are boulders or biogenic reefs.

Rugosity The roughness or irregular texture of the seabed.

Saddle Broad pass, resembling in shape a riding saddle, on a ridge or between contiguous seamounts.

Sand dunes See "Dune."

Sand waves Replaced by the term "dune" in modern usage. Undersea "sand dunes" that may be static or move under the influence of waves and tides and are subperpendicular to the current.

Sand Sediment grains 0.063–2 mm diameter.

Scavenger Animals that feed on dead animal material, and sometimes also drift algae.

Sea-hill A seabed feature elevated more than 100 m from the surrounding seabed. Smaller than a knoll and seamount.

Seamount An underwater mountain greater than 1000 m in relief above the sea floor, characteristically of volcanic origin and conical form.

Seascapes Undersea landscapes. Topographic features that reoccur geographically (e.g., seamounts, estuaries, canyons, and plains).

Sedentary Animals that do not normally move, but can if required (e.g., sea anemones, mussels).

Sediment Ecologically are so-called "soft substrata" with infauna, and usually some epibiota.

Sediment processes Processes that affect the creation, erosion, transport and deposition of sediments.

Sediment sink A site where there is a net accumulation of sediment.

Sediment transport Movement of sediment in the water column or on the seabed.

Seismic data Acoustic data derived from a low frequency (less than 12 kHz) seismic sound source, typically using compressed air or electric pulses, that produce an image of sediment layers comprising the seabed.

Seismic waves Pressure waves generated by volcanic eruptions, earthquakes or explosions that propagate through the earth's crust; waves that are detected and recorded by seismographs.

Sessile Animals attached to the substratum.

Shoal Offshore hazard to surface navigation that is composed of unconsolidated material such as gravel or shell.

Side scan sonar An acoustic remote-sensing method of identifying seabed features using a sonar two-fish that emits sound waves at a low angle of incidence to the seabed.

Sill Seafloor barrier of relatively shallow depth restricting water movement between adjacent basins. In oceanography, the sill depth signifies the depth of water that a water mass must achieve in order to pass between basins.

Silt Particles of between 0.0039 and 0.0625 mm in diameter. Larger than clay, smaller than sand. Mud is comprised of clay and silt.

Sonar Derived from the phrase "sound navigation and ranging"; method or equipment for determining the water depth by underwater sound (echolocation).

Sound A deep embayment located between offshore islands and the mainland or between islands.

Speciation Process of a species being formed from other species.

Species richness The number of species that occurs in an area or collection of samples.

Species saturation The idea from Island Biogeography Theory that the number of species in an area has a maximum determined by the rate of local colonization and extinction; such that if a new species becomes established then an existing species will go extinct.

Species turnover The change in species composition over time and/or space. See "Beta-diversity."

Splash or spray zone Area of upper seashore not submerged at high tide but sprayed at high tide by breaking waves.

Spring tide The maximum amplitude of the astronomical tide (every 14 days corresponding with the new and full moon)

Stenohaline Organisms limited to a narrow range of salinities. The opposite of euryhaline.

Stepping stones Small areas of habitat that enable a species to disperse across otherwise unsuitable environment.

Storm surge A major rise in sea level above the normal range due to episodic events such as low atmospheric pressure and high winds.

Strait A channel or gap between an island and the mainland, or two headlands.

Strandline Area of upper seashore where loose seaweed and other floating debris is deposited by the falling tide.

Stratified In water, where one or more horizontally extended water masses lie on top of each other. They are separated by boundaries based on differences in temperature (thermocline), density (pycnocline), and/or salinity (halocline). See also "Front."

Subduction zone Adjacent to active plate margins, a place where ocean crust collides with and is subducted beneath continental crust or another ocean to create a ridge and ocean trench complex.

Sublittoral Below the littoral, never exposed to air. Same as subtidal. Includes the infra- and circa-littoral.

Sublittoral fringe Transition zone where littoral and sublittoral species occur, sometimes determined by differences in neap and spring low tides.

Substrate A substance used as a food source by organisms or enzymes. This usage has been extended to any surface a plant or animal lives upon, whether biotic or abiotic materials. Ecological use favors use of substratum (singular) and substrata (plural) where the surface is for attachment rather than a food source.

Substratum(a) Surface (singular) to which an organism grows on or amongst. Substrata is plural.

Supralittoral Uppermost part of shore affected by wave splash but not regularly submerged by the sea. Also called the supratidal, epilittoral, splashzone, spray zone, littoral fringe, and strandline.

Surrogate A measurable entity that is used to represent, or substitutes for, a more complex element of biodiversity that is more difficult to measure.

Suspension feeding Animals that feed on water-borne particulate material, which may include plankton.

Swale A low lying marshy area, such as between sand dunes.

Symbiotic Organisms that both benefit from their association.

Sympatric speciation Species that evolve within the same geographic area, perhaps due to specialization on different food resources or seasonal differences in growth or reproduction.

Taxon (Taxa) A distinct category of organism at any level in the taxonomic hierarchy from species to family to kingdom. Taxa is plural.

Terrace Relatively flat horizontal or gently inclined surface, sometimes long and narrow, which is bounded by a steeper ascending slope on one side and by a steeper descending slope on the opposite side.

Terrain The physical land surface and seabed.

Terrigenous Derived from the land, as in terrigenous sediment. Usually siliciclastic rather than calcareous or calciclastic.

Tidal range The amplitude of the tides in a particular area due to astronomical (gravitational forces of the sun and moon) forcing.

Topography The form, relief, shape and texture of the earth's surface, including the seabed.

Trench Long, narrow, characteristically "V"-shaped in section, very deep and asymmetrical depression of the sea floor, with relatively steep sides.

Trophic level The position of an organism in the food chain or "food pyramid," determined by the number of transfers of energy that occur between the non-living energy source and that level.

Trough Long depression of the sea floor characteristically flat bottomed and steep sided and normally shallower than a trench.

Tsunami A very fast moving oceanic wave, initiated by an underwater disturbance, such as an earthquake, volcanic eruption or slumping (Japanese for "harbor wave").

Tubicolous Animals that live in tubes.

Turbidity current A dense mixture of suspended sediment and water that flows downslope under the influence of gravity. Normally constrained to the continental slope and attributed to the formation of submarine canyons.

Upwelling An oceanographic process by which water rises from the lower depths upwards into shallow surface waters.

Vagile Animals that move around.

Vagrant Animals outside of their normal habitat or environment. They may be searching for new habitats or mates.

Valley Relatively shallow, wide depression, the bottom of which usually has a continuous gradient. This term is generally not used for features that have canyon-like characteristics for a significant portion of their extent.

Vicariance The geographic separation of a population or biota by climatic and/or geological events, typically resulting in the formation of new species.

Water mass A volume of water that has defined salinity and/or temperature characteristics.

Wave refraction Modification of the angle of waves by seabed features.

Wave rose A method of showing the size and direction of waves based on the frequency of occurrence in different quadrants of the compass.

Winnowing Removal of fine material from coarse ones by winds or currents.

Zones Horizontal areas of vertical height above, and depth below, sea level which has a characteristic fauna and flora. Also called étage.

Zooplankton Planktonic animals; i.e., Animals that live in the plankton and which are unable to move against regional currents.

Abstract

The natural sciences are rich in concepts. The usage of the terminology to name these concepts may change over time and due to mistaken or extended use of terms. Some are adopted from a particular vernacular language where the word may have a different meaning than its use in science (e.g., endemic) and some scientific terms may become used in wider society (e.g., ecosystems). Alternative meanings of the same words can cause confusion, especially among students and nonspecialists not familiar with the nuances of usage. It is thus useful to provide a glossary of how a community defines its terminology at the present time. Here we provide definitions of about 300 terms commonly used in marine ecology, oceanography and geology.

Introduction

The natural sciences are rich in concepts. The usage of the terminology to name these concepts may change over time and due to mistaken or extended use of terms. Some are adopted from a particular vernacular language where the word may have a different meaning than its use in science (e.g., endemic) and some scientific terms may become used in wider society (e.g., ecosystems). Alternative meanings of the same words can cause confusion, especially among students and nonspecialists not familiar with the nuances of usage. It is thus useful to provide a glossary of how a community defines its terminology at the present time. This glossary was developed as a collaboration between the scientists of the GEOHAB (Marine Geological and Biological Habitat Mapping) and WoRMS (World Register of Marine Species) communities. It was published online on WoRMS from 2010 and comments by users led to additions and corrections.

The glossary does not intend to provide a review or history of all uses of particular terms, nor how they may be used in other fields of research. The definitions are those recommended for use in marine biology, ecology, oceanography, and geology. The glossary excludes terminology specific to the following areas: names of marine species and higher taxa (see WoRMS); place names (see gazetteers at MarineRegions.org and GEBCO); taxonomy; physiology; archaeology; fisheries; legal and regulatory terms; acronyms.

Abstract

Understanding the ocean environment at a global scale has never been so important due to the need to predict the effects of climate change and its consequences for biodiversity, including the ecosystems and species which are influenced by, and in turn alter, their environment. Here we present world maps of long-term (annual and decadal) averages of the following ocean environment variables: seabed depth and slope; sea surface and near seabed temperatures; current velocity and wind speed; wave and tide height; dissolved, saturated and utilized oxygen; effects of water transparency on photosynthetic radiation and depth; phytoplankton productivity and calcite; nutrients; salinity, pH, and suspended particulates; and summer and winter ice cover. We point out some of their key geographic features, correlations between variables, and interrelationships.

Introduction

The ocean, covering 71% of the planet (Costello et al., 2010), plays an important role in regulating the global climate through the interaction of water with the atmosphere. While in the oceanic environment, a number of environmental conditions affect the mobility, growth, survival, and productivity of biological organisms. Among these variables, the depth, availability of light, oxygen, water current, salinity, temperature, and nutrients influence species distributions across the ocean. Moreover, the three-dimensional nature of the oceanic environment makes the environmental conditions vary from location to location both horizontally and vertically (Sayre et al., 2017). Animal life occurs throughout the oceans, from the ice-covered polar regions to hot hydrothermal vents, and deepest trenches (Rothschild and Mancinelli, 2001; Zeppilli et al., 2018). To characterize the ocean environment we need to understand how different environmental parameters interact between each other.

Typically, marine environmental data have been gathered from combinations of observations and modeled values of ocean surface (e.g., wave height), water column (e.g., temperature, salinity, oxygen), seafloor measurements (e.g., depth) (Valavanis et al., 2008), in situ observations (e.g., survey cruise, AUV and Argo floats), and remotely sensed satellite data (e.g., chlorophyll-a, surface temperature) (Costello et al., 2017). In this article, we discuss the environmental characteristics of the world ocean based on an interpretation of selected publicly available global environmental data (Basher et al., 2018).

Statistics

The color gradients on the maps show the relative high and low values of each environmental variable (Figs. 1 and 3–6). The actual average, maximum, minimum and variation are provided in Tables 1 and 2, and positive and negative correlations between them in Table 3. Because the standard deviation and error are dependent on the mean, we also provide the coefficient of variation. It is important to note that these values are dependent on the spatial resolution of the underlying data. The maps are at a spatial resolution of 5 arc minute (about 9.2 km in the equator). Thus, local areas may have more extreme maxima and minima than stated in the Tables. For example, areas with cliffs will have higher slopes, narrow channels higher currents, and enclosed sheltered shallow bays may have higher temperatures.

Fig. 1 World maps of (A) bathymetry, (B) slope and (C) distance to land. Color scales from *red to blue* indicate (A) shallow to deep, (B) high to low slope, (C) far to near coast. See **Table 1** for range of values of each variable. Data from Basher, Z., Bowden, D. A. and Costello, M. J. (2018). Global Marine Environment Datasets (GMED). World Wide Web electronic publication. Version 2.0 (Rev.02.2018). Available at <http://gmed.auckland.ac.nz> (Accessed 2 March 2019).

Bathymetry

Depth is one of the most important environmental variables because it correlates with almost all other environmental parameters in the ocean. The deepest depth is 10,294 m (**Table 1**). The northern hemisphere has a larger area of continental shelves, and more ocean close to land compared to the southern hemisphere (**Fig. 1**). Light penetration, temperature, and nutrient availability in the water column decline with depth at any particular point (**Fig. 1, Table 3**). In addition, the variability of environmental variables declines with depth, for example for temperature (**Fig. 2A**) (**Costello et al., 2018**). Most of the ocean is remarkably flat, with a slope of less than one degree (**Table 1**), and areas with relatively high slope indicate the presence of mid-ocean ridges, underwater volcanic

Fig. 2 Depth gradients of (A) temperature, (B) oxygen, and (C) salinity, shown as standard deviation (*dotted line*), coefficient of variation (*green*) and average (*solid line*). Modified from Costello, M. J., Basher, Z., Sayre, R., Breyer, S., and Wright, D. J. (2018). Stratifying Ocean sampling globally and with depth to account for environmental variability. *Scientific Reports* 8(1), 11259.

activity, and seamounts. There are over 1 million sea-hills, and some 70,000 seamounts, that is hills rising over 1 km from the seabed (Costello et al., 2010).

Temperature

The temperature of the ocean depends on the amount of solar energy absorbed by the ocean surface. Through its direct effect on biochemistry and physiology, and indirect effect on environmental conditions, temperature regulates biological processes and diversity in the ocean. Tropical oceans receive a lot of direct sunlight for much of the year, while polar regions only receive sunlight in summer. Tropical temperatures are about 25 °C to 30 °C and polar -2 °C to $+2$ °C. With depth, temperature rapidly drops until about 1000 m and then remains relatively consistent all the way to the seabed (Fig. 2A). Thus, the warmest waters are near the equator and coldest waters are near the poles (Fig. 3), while the deep sea is as dark and cold as a domestic fridge (<4 °C).

Fig. 3 World maps of long-term average sea temperature at the (A) surface, (B) seabed and (C) water column average (from surface to seabed). Color scale from *red to blue* indicates warm to low temperature. See [Table 1](#) for values of each variable. Data from Basher, Z., Bowden, D. A. and Costello, M. J. (2019). GMED: Global marine environment datasets for environment visualisation and species distribution modelling. *PeerJ* (In Review).

Water movement

Global winds drag on the water's surface ([Fig. 4A](#)). As a result of the Coriolis Effect (due to the Earth's rotation) circulating air and ocean currents are deflected toward the right in the Northern Hemisphere and toward the left in the Southern Hemisphere. The major surface ocean currents deflect in a clockwise spiral in the Northern Hemisphere and anti-clockwise in the Southern Hemisphere. These major spirals of ocean-circling currents are called gyres and occur north and south of the equator.

Currents are largely driven by wind, tides and the global circulation of water ([Fig. 4B](#)). As water is denser than air, it has more momentum and once in sets in motion, it easily keeps flowing. Surface currents of the ocean are driven by global wind systems that

Fig. 4 World map of (A) wind speed, (B) surface currents, (C) wave height, and (D) tide height. Color gradients from red to blue indicate fast and slow for (A) and (B), and high to low for (C) and (D). See [Table 1](#) for range of values of each variable. Data from Basher, Z., Bowden, D. A. and Costello, M. J. (2019). GMED: Global marine environment datasets for environment visualisation and species distribution modelling. *PeerJ* (In Review).

are fueled by the energy from the sun. Currents play an important role in moving water between the poles and the tropics. Currents also move food and nutrients from the coast further out into the sea. Currents flowing along the western side of ocean basins (e.g., Gulf Stream) are typically stronger, deeper, and narrower due to the rotation of the Earth, which piles water along the western edge of land masses, while currents flowing along the eastern side of ocean basins are weaker, wider, and slower. This phenomenon is known as the western intensification of currents (Thurman et al., 2013). These effects can be seen as currents move along the north-west Atlantic and Pacific oceans (Fig. 4B). Long-term positions of major currents in the ocean have changed over millennia due to plate tectonics, climate, and periodic astronomical events such as asteroid impacts. These factors influenced the shape of ocean basins and defined the path and location of modern-day currents.

Unimpeded by land masses, the strongest winds and currents are in the Southern Ocean and known as the Antarctic Circumpolar Current (Fig. 4B) (Rintoul et al., 2001). Strong winds also prevail in the northern latitudes, but are weaker in the Arctic and equatorial latitudes. The equator is bounded by latitudes with very high and low currents. The region where Pacific waters pass through the islands of Papua New Guinea and Indonesia to the Indian Ocean has the highest diversity of marine species in the world, and is part of the Coral Triangle region (Asaad et al., 2018a,b, 2019).

Vertical movements of the ocean include those due to waves and tide. Together with the current, wave action is one of the most significant environmental conditions affecting life in the sea. Waves are higher in coastal waters due to the effect of shallowing depths, and the high waves due to strong winds in the northern and southern latitudes can be seen in Fig. 4C. The impact of waves generally reduces with depth (Fig. 4C). In contrast, tidal movements are a function of the Earth's rotation and currents, and tend to be higher where they are forced by current movements (e.g., north-east Atlantic and Pacific oceans) and are constrained by narrowing land barriers (e.g., seas in the west north Pacific) (Fig. 4D). Tidal height is highest on the eastern northern hemisphere oceans (Fig. 4D).

Oxygen

Dissolved oxygen in seawater is absorbed from the atmosphere and is a byproduct of photosynthesis. As a result, most oxygen-rich water is found near the surface in the sunlit (also called the photic and epipelagic) zone, which where all plants and most marine organisms live (Costello and Chaudhary, 2017). Dissolved oxygen has a strong relationship with temperature (Garcia et al., 2005; Table 3), which is reflected in polar oceans having high concentrations of dissolved oxygen compared to the tropics (Fig. 5A). Below the photic zone there is no photosynthesis or absorption from air, and the respiration of animals and microbes consumes oxygen. Thus, oxygen declines with depth (Table 3, Fig. 2B), and large areas of deep water in the eastern Pacific and Indo-Pacific region are low in oxygen (i.e., hypoxic) (Fig. 5C). The near seabed hypoxic regions have high "utilized oxygen" (Fig. 5D), mirroring the areas of low oxygen.

The high phytoplankton productivity of the Arctic results in high oxygen saturation, and the relatively high consumption of oxygen in the warm tropics leads to lower saturation (Fig. 5C).

Light Transparency

The euphotic depth is where the amount of light (irradiation) sufficient for photosynthesis, called photosynthetically active radiation (PAR), is 1% of its surface value (Morel and Berthon, 1989). This depth is measured by satellite as a function of water clarity, and thus its depth depends on the concentration of particles suspended in the water column (Table 3). These particles are highest near the coast (Fig. 6A). Phytoplankton biomass tends to be lower in the tropics because growth is nutrient (rather than light) limited, and thus water clarity (or light transparency) and PAR are highest in offshore tropical latitudes (Fig. 6B). Thus, productivity was positively correlated with the salinity, Particulate Organic Carbon (POC), and diffuse attenuation coefficient (DAC) (Fig. 6, Table 3). When more suspended particulate matter is present (i.e., coastal waters), the depth of this photic zone will be shallow, only a few meters. In offshore waters, where coastal landscape influences are negligible and concentrations of plankton are sparse, the photic zone is as deep 142 m (Table 1) (Fig. 6C), but locally may extend to 200 m. Polar regions generally have shallower euphotic depths value due to the presence of sea ice. Furthermore, the nutrients (nitrate, phosphate, and silicate) showed negative correlation with temperature and depth, which may indicate why photosynthetically active radiation (PAR) was greater in warmer waters (Table 3).

Productivity

Plant growth depends not only on sufficient light, but also sufficient macro-nutrients, primarily oxidized nitrogen and phosphorous. Nitrogen is comprised of two oxidized forms, nitrate and nitrite, of which nitrate dominates, and ammonia. Ammonia is highly volatile and rapidly utilized by plants and thus of low concentration in unpolluted seawater. Thus nitrate is the primary indicator of nitrogen available to plants. In contrast to freshwaters where phosphorous limits plant growth, in seawater plant growth is generally nitrogen limited. Thus plant productivity, in this case phytoplankton because the data are derived from satellite observations of changes on ocean color, is highest near the coasts where freshwater runoff (including rivers) contributes nitrogen (Fig. 6D). Upwellings of seawater from deep nutrient rich waters to shallow depths also contribute to productivity. In addition, diatoms, one of the primary groups of phytoplankton, require silica to build their cell walls, and thus silica is essential for their growth.

Fig. 5 World maps of oxygen as (A) surface concentration, (B) surface saturation, (C) seabed concentration, and (D) utilized at the seabed. Color gradients from *red* to *blue* indicate more to less. See [Table 1](#) for range of values of each variable. Data from Basher, Z., Bowden, D. A., and Costello, M. J. (2019). GMED: Global marine environment datasets for environment visualisation and species distribution modelling. *PeerJ* (In Review).

Fig. 6 World maps of the effects of light transparency in the ocean, expressed as the (A) diffuse attenuation coefficient, (B) photosynthetically active radiation, (C) Euphotic layer depth, and (D) phytoplankton productivity. Color gradients of from *red to blue* indicate more to less. See [Table 1](#) for range of values of each variable. Data from Basher, Z., Bowden, D. A., and Costello, M. J. (2019). Table 1 Descriptive statistics for the physical environmental layers.

Layers	Minimum	Maximum	Mean	Standard deviation	Standard error	Coefficient of variation
Physical						
Depth (m)	10,294	0	3440	1739	0.72	0.5
Slope (degree)	0	21.65	0.98	1.22	0	1.2
Land distance (km)	1	2774	666	554	0	0.8
Ice cover (annual) (% 0–1)	0	1	0.12	0.27	0	2.18
Ice cover (May–October)	0	1	0.12	0.28	0	2.29
Ice cover (November–April)	0	1	0.11	0.28	0	2.56
Wave height (m)	0	7	0.28	0.99	0	3.51
Wind speed (m.s ⁻¹)	0	12	7	1.96	0	0.27
Tide average (m)	0	6.4	0.5	0.45	0	0.97
Current (m.s ⁻¹)	−0.9	1	0	0.1	0	16.16
Euphotic layer bottom depth (m)	7	142	72	24	0.01	0.33
Diffuse attenuation coefficient (m ⁻¹)	0.02	0.89	0.06	0.04	0	0.79
Temperature (°C)	−1.0	31.5	14.4	10.94	0	0.76
Temperature maximum	−1.0	35.2	16.8	11.18	0	0.66
Temperature minimum	−2.0	30.8	12.5	10.68	0	0.86
Temperature range	0	27.8	4.1	3.02	0	0.74
Temperature (May–October)	−2.1	30.7	14.4	11.33	0	0.78
Temperature (November–April)	−2.1	30.7	14.4	11.12	0	0.77
Average water column temperature	−2.3	26.0	5.6	3.63	0	0.65
Seabed temperature	−2.08	29.5	2.0	3.86	0	1.97
Salinity (PSS)	0	41	33.6	2.5	0	0.07
Average water column salinity	6.3	40.6	34.5	1.91	0	0.06
Photosynthetically active radiation (Einstein.m ⁻² .day ⁻¹)	0	64.82	34.13	9.06	0	0.27

All values are in annual means and refer to the ocean surface unless noted otherwise. The Standard Deviation (SD) is used to quantify the amount of variation in the data. The Standard Error adjusts the SD for the number of samples taken. The Coefficient of Variation (CV) is the SD as a percentage of the sample mean and is thus independent of the mean and units in which the measurement has been taken.

Data from Basher, Z., Bowden, D. A. and Costello, M. J. (2019). GMED: Global marine environment datasets for environment visualisation and species distribution modelling. *PeerJ* (In Review).

In the Southern Ocean and parts of the north Pacific, nutrients are exceptionally high (Fig. 7A–C), this is because a micronutrient, iron, is limiting plant growth. In these locations iron derived from land runoff, including oceanic islands, and brought to the surface in feces of marine mammals, may increase productivity at local spatial scales (Frey et al., 2014).

Calcite is an indicator of the growth of plankton that have calcified shells, notably coccolithophore phytoplankton and foraminifera (protozoan animals). Their growth is highest in the tropics (Fig. 7D). It is lower in temperate latitudes and regions of upwelling due to these taxa being outcompeted by the faster growing diatoms (Culver and Buzas, 2000; Sarmiento et al., 2004; Gregg and Casey, 2007).

Salts, pH, and Particulates

The salinity (or saltiness) of seawater refers to the amount of inorganic salts dissolved in the water. Although most seawater has a salinity of ~ 35 , it can reach up to almost 40 in some areas such as the Mediterranean and Red Sea (Fig. 8A). The units of salinity measurement have changed over time, including g/kg, ppt (parts per thousand), ‰, and PSU (practical salinity units), but it is now preferred to use the PSS (practical salinity scale) and just state the numerical value.

In estuaries, salinity is typically low, as there is regular input of freshwater, typically from a river. Salinity is higher around the tropics of Cancer and Capricorn, where the evaporation rate is high and precipitation (rainfall) is low. It is lower in high latitudes due to low evaporation rates combined with high precipitation and runoff as well due to the melting of icebergs. In the tropics, surface salinity is higher and rapidly decreases from ~ 200 to 1000 m where it stabilizes at around 35 (Thurman et al., 2013). At high latitudes the pattern is inverted: surface salinity is lower at the surface than at depth (Figs. 2C and 8A).

pH varies very little in seawater (Table 2) compared to freshwaters. It is relatively stable in open ocean, and varies most where freshwater runoff meets the ocean (i.e., estuaries) (Hofmann et al., 2011). The world map shows pH is generally higher in the Pacific compared to other oceans (Fig. 8B).

The concentration of particulate matter in seawater, presented as total suspended solids, is higher near land reflecting freshwater inputs (Fig. 8C). Similarly, Particulate Organic Carbon (POC) indicates organic carbon is highest near where estuaries or rivers enter the ocean (Fig. 8D). This is due to high phytoplankton growth and productivity increasing organic carbon concentrations (Harrison and Cota, 1991).

Ice

Sea ice is frozen seawater that floats on the ocean surface. It forms in both the Arctic and the Antarctic in each hemisphere's winter and retreats in the summer but does not completely disappear (Fig. 9). Floating ice caps have a profound influence on the polar environment, influencing ocean circulation, weather, and regional climate. The influence of sea ice coverage is not just regional, it's global. As ice crystals form in the surface ocean they expel salt which increases the salinity of water under the ice. This creates cold dense (higher salinity), oxygen-rich, water which sinks to the ocean floor and flows toward the equator. This flow drives the formation of the ocean circulation system, also called the global ocean conveyor belt (Broecker, 1991): a mechanism which maintains the global heat balance.

Conclusions

Here we have mapped a wide range of ocean environmental variables and shown how they vary quantitatively and correlate with each other (Tables 1–3). Comparing the maps show how they relate to each other geographically. These facts, and knowing their interrelationships, are essential to predict the effects of climate change on our oceans, and the effects of human activities on biodiversity. Understanding these spatial relationships, including the effects of plant growth on nutrients, oxygen and calcite, within the water masses created by the forces of energy (currents, wind, tides, temperature) and water density (salinity), within the confines of depth and topographic gradients and distance to land, has never been so important.

Abstract

Razor clams (Pharidae and Solenidae, Mollusca) are ecologically and economically important deep-burrowing bivalves. They are distributed in shallow waters of the tropical, subtropical, and temperate seas. The North-West and the Indo-West Pacific has the highest species richness (about 85% of all species) mostly in the Sea of Japan, China Sea, the Gulf of Thailand, and the Andaman Sea. Their species composition forms 16 biogeographic regions which concur with existing marine biogeographic hypotheses. More than half of the species are endemic to these biogeographic regions. This is an exceptionally high rate of endemism in the oceans and suggests little gene flow between populations. Species richness increases from the cold temperate to intermediate latitudes and dips near the equator following the mean sea surface temperature. Species richness decreases with temperature range, chlorophyll-*a* concentration, and primary productivity over all latitudes, but increases with ocean area in the Northern Hemisphere. Most species are predicted to shift their distribution ranges poleward in the future due to global warming. Thus the mid-latitude peaks of species richness will move further apart, increasing the dip in richness near the equator.

Biology and Ecology

Systematics and Taxonomy

The Solenidae family of razor clams has three genera, *Solen* Linnaeus, 1758, with more than 65 species, *Solena* Mörch, 1853 with two species, and *Neosolen* Ghosh, 1920 with one species *Neosolen aquaedulcioris* (Ghosh, 1920), within the superfamily Solenoidea in Subclass Heterodonta, and Class Bivalvia (Cosel, 1990; Bouchet et al., 2010; MolluscaBase, 2018). At first, *Solena* Browne was classified as a subgenus of *Solen* Linné Cosel (1990). Later, Ghosh (1920) included nine genera in the Solenidae, namely *Solen* Linné, 1758; *Solena* Browne, 1756; *Neosolen* Ghosh, 1920; *Ensis* Schumacher, 1817; *Ceratisolen* Forbes and Hanley, 1848 (= *Pharus*); *Subcultellus* Ghosh, 1920 (= *Phaxas*); *Cultellus* Schumacher, 1817; *Pharella* Gray, 1854; and *Siliqua* Mühlfeld, 1811 (Cosel, 1990). Later, Cosel (1990) included two genera *Solen* Linnaeus, 1758 and *Solena* Mörch, 1853 within the Solenidae, and he classified *Ensisolen* Habe, 1977 and *Neosolen* Ghosh, 1920 (with only one species *aquaedulcioris*) as subgenera of *Solen*. He also classified the now extinct subgenera *Eosolen* Stewar, 1930 and *Plectosolen* Conrad, 1866 under *Solena* from fossil records. The fossil records of Solenidae are rare because of their fragile shells, but there are some records from the late Eocene about 40–42 million years ago (Mya) (Cosel, 1990).

Shell Morphology and Anatomy

Solen shells range from 50 to 120 mm in length, can be thin and translucent to opaque, straight to slightly curved, and short to narrow. In cross-section they can be oval to tubular, truncated or with rounded anterior and posterior ends. The shells have thin elongate valves with a wide gape at each end. Each valve has one cardinal tooth, an external ligament, and a glossy periostracum (Fig. 1) (Cosel, 1989, 1990; Saeedi et al., 2013).

Solenid shells do not close completely, so posterior and anterior ends of the shells are always open (Saeedi et al., 2009). A long, powerful foot and elongate shell enables razor clams to rapidly burrow into substratum (Saeedi et al., 2009). They have two fleshy siphons which extend into the water column to pull in water to feed on plankton. These have an autonomy function which is an anti-predator adaptation. This means they can lose their siphons when attacked by predators, and then the siphon can regrow (Saeedi et al., 2009, 2013).

Fig. 1 Internal view of both valves of *Solen dactylus*, half-schematic drawing. 1: hinge; 2: ligament; 3: anterior adductor muscle scar; 4: anterior retractor muscle scar; 5: pallial muscle scar; 6: posterior adductor muscle scar; 7: pallial sinus; 8: ventral limb of pallial sinus; 9: dorsal limb of pallial sinus. (A) Total shell length; (B) Greatest width of shell; (C) Distance of the innermost point of the pallial sinus to the posterior margin; (D) Length of posterior adductor scar; (E) Distance between posterior adductor scar and pallial sinus; (F) Ligament length; (G) Length of anterior adductor scar; (H) Anterior furrow shell length. Presence of anterior shell furrow was also recorded.

Growth and Reproduction

Growth rate in Solenidae has been measured in *Solen dactylus* and *Solen cylindraceus*, which grow 20–30 mm and 23 mm per year, respectively depending on their age (Saeedi et al., 2009; Nel et al., 2013). Growth rate in Solenidae after the first year of age becomes increasingly slower as the clams become reproductive.

The sexes are separate in Solenidae and the species *Solen strictus*, from Hong Kong, *S. marginatus* from Spain, and *S. dactylus* from Iran spawn only once a year (Gribben, 2005; Remacha-Trivino and Anadon, 2006; Saeedi et al., 2009). They release large volumes of gametes that lead to synchronized external fertilization and subsequent recruitment (Saeedi et al., 2009).

Solen marginatus has a planktonic larval period of less than 2 weeks and requires sandy and muddy substrata for juveniles to settle into (da Costa et al., 2011). In at least this species, the relatively large eggs have high levels of stored nutrients and a short larval development time of only 8 days (da Costa et al., 2011).

Habitat

Solenidae inhabit the lower portions of sandy-muddy intertidal zones down to a depth of 110 m (Saeedi et al., 2013, 2017). However, most species are found in shallow waters (0–30 m) where they can constitute an important component of in-faunal soft-bottom communities (Cosel, 1990). Annelids, crabs, gastropods, and other borrowing bivalves are the most common cohabitants of these soft-bottom communities (Lassuy and Simons, 1989). Only two species, *Solen annandalei* and *Solen kemp* are known to tolerate low salinity conditions, namely in Chilka Lake, India, with 0.5 to 30 ppt salinity at an average depth of <5 m (Cosel, 1990; Nayak et al., 2004).

Biogeography

Members of Solenidae are distributed worldwide with the exception of the polar regions and some oceanic islands such as New Zealand (Saeedi et al., 2017; Cosel, 1990) (Fig. 2). About 45 *Solen* species are distributed in the tropical western Pacific Ocean from Japan and China to the Indian Ocean and Australia (Cosel, 1989, 1990; Saeedi et al., 2009, 2013; Guerra et al., 2011). New species

Fig. 2 Distribution of Solenidae species showing 16 biogeographic regions (solid black lines) derived from sample locations (colored points, each color represents one species). South-west Atlantic (A); west Africa (B); north-east Atlantic and Mediterranean (C); western Australia (D); eastern Australia (E); north-east Pacific (F); central-east Pacific (G); north-west Atlantic (H); Caribbean Sea (I); south-west Indian Ocean (J); north-west Indian Ocean (K); Red Sea and Gulf of Aden (L); north-west Pacific (M); Indo-West Pacific (N); south-east Pacific (O); New Caledonia (P).

Fig. 3 Number of total Solenidae species (plus one) (hollow bars) versus mean sea surface temperature (solid line) in 5 degree latitudinal bands.

are still to be expected in the Indian Ocean and the western Pacific, the Coral Triangle (mainly Indonesia, Philippines, Papua-New Guinea), and northern Australia (Cosel, 1990). Saeedi et al. (2017) studied the global biodiversity and biogeography of Solenidae and she discovered a bimodal global latitudinal species richness for the first time in Solenidae (Fig. 3) and later in all marine species (Chaudhary et al., 2016; Saeedi et al., 2017). Global patterns of Solenidae species richness increased from the poles to intermediate latitudes and dipped near the equator, exhibiting a strongly bimodal pattern that is likely to be temperature driven (Saeedi et al., 2017) (Fig. 3). A non-linear relationship between species richness and mean sea-surface temperature was compatible with this bimodal pattern (Saeedi et al., 2017). Cluster analysis of similarity patterns of species composition (i.e., presence of Solenidae species) for 5 degree latitudinal-longitudinal grid cells showed 16 significant biogeographical regions that concurred with existing marine biogeographical hypotheses (Fig. 2). More than half of the species were endemic to specific biogeographical regions (Saeedi et al., 2017).

Comparison with models of future temperatures scenarios found that most Solenidae species were predicted to shift their distribution ranges poleward due to climate warming; that is, species in the northern hemisphere would shift northward and southern species southward (Saeedi et al., 2016). Model results predicted that the mid-latitude peaks of species richness will move further apart, increasing the dip in richness near the equator, due to global climate change (Saeedi et al., 2016).

Ecological Importance

Of the 242,954 accepted marine species, 48,048 are marine molluscs (Bouchet, 2006; WoRMS, 2018). Molluscs significantly contribute to the food web as herbivores and predators. The filter-feeding of bivalves, such as razor clams, can improve water quality (Dumbauld et al., 2009). Razor clams' are also prey to crabs, sea birds, and demersal fish especially on newly recruited razor clams

when they have the highest mortality rates (Guerra et al., 2011; Lassuy and Simons, 1989). However, razor clam deep-burrowing behavior (about 30 cm into the substrate) hides them from many predators. The average density and biomass reported for Pharidae is about 60–80 individuals m^{-2} and 1–3 kg m^{-2} respectively (Guerra et al., 2011), but biomass in Solenidae has not been reported so far. They can also play a role in the nitrogen cycles of surface waters by excreting ammonium which is used by algal populations as a nitrogen source (Lewin et al., 1979).

Razor clams can be bio-indicators of heavy metals such as Mg, Fe, Cu, and especially Zn in their environment (Saeedi et al., 2012). However, *Solen brevis* (in Pahang, Malaysia), *S. dactylus* (in Bandar Abbas, Iran), and *S. regularis* (in Moyan and Serpan, Sarawak) remained safe for human consumption because metal concentrations were under the limits established by national and international health standards (Kanakaraju et al., 2008; Kamaruzzaman et al., 2010; Saeedi et al., 2012). Only one species, *Neosolen aquaedulcoris*, is assessed in the IUCN Red List of Threatened Species, and it was considered to be of “Least Concern” status (Bogan, 2012).

Societal Importance

Approximately 11% (6.6 million tonnes) of all marine species exploited by the fishing and aquaculture industry were molluscs (Yearbook, 2018; FAO, 2011). In 2009, molluscs accounted for 38% (13 million tons) of the total harvest of the global mariculture industry (FAO, 2011, #274), most of which were mussels and clams. Although the contribution of Pharidae and Solenidae to this is likely minor, they are relatively high value per unit weight. Members of Solenidae are mostly consumed as seafood in Europe, North America, East Asia, and South Asia (Saeedi et al., 2013; Guerra et al., 2011). In some countries like Iran people harvest Solenidae species as bait for fishing and as a food source in shrimp culture (Saeedi et al., 2009).

In an economic context, the sharp rise in price of razor clam meat as a source of nutrition for humans, particularly for Pharidae and Solenidae, exemplifies the increased importance of bivalves on global commercial markets (Fernández-Tajes and Méndez, 2007). The import value of razor clams in central and northern European markets reached EUR550 million in 2004 (Fernández-Tajes and Méndez, 2007; da Costa and Martínez-Patino, 2009; da Costa et al., 2011). In the European Union, Spain alone accounts for approximately 43% of the total volume of imported razor clams (Fernández-Tajes and Méndez, 2007).

There are different harvesting methods to collect razor clams such as digging, dredging, electric fishing, salting, and using fishing tools with a hook in the end (Saeedi et al., 2009; Guerra et al., 2011). Razor clams have been over-harvested around the world especially in Europe (Fernández-Tajes and Méndez, 2007) and southeastern Asia where there are no regulations in place to protect their populations (Saeedi et al., 2009).

A better understanding of the reproductive biology of razor clams could assist fisheries managers in reducing harvesting pressure at specific locations. For example, *Solen regularis* (Sarawak) (Rinyod and Rahim, 2011), *S. dactylus* (Iran) (Saeedi et al., 2009), and *S. marginatus* (Spain) (Remacha-Trivino and Anadon, 2006), spawn in winter and rest in early spring and summer. Established spawning behaviors of these species have shaped regulations that limit harvesting to nonspawning seasons (Saeedi et al., 2009). Similar knowledge contributed to more sustainable management of razor clam fisheries and potential species for aquaculture in Europe (da Costa et al., 2011). Fisheries need to take care not to deplete populations of razor clams because their high degree of endemism makes them susceptible to over-fishing and suggests little recruitment from distant populations.

Abstract

Bryozoans are common animals in marine benthic (seabed) ecosystems, and also occur in freshwater rivers, with 6063 and 108 extant species in each environment respectively. There are 17,867 fossil species described. They are distributed across the oceans with a relatively high diversity on the Antarctic shelf. They are colonial suspension filter feeders with a calcified skeleton, a wide variety of life cycles and growth forms, and are well represented in the fossil record.

Biology

Taxonomy and Systematics

Bryozoans are a phylum of aquatic invertebrates containing around 24,000 extant and fossil described species (Bock and Gordon, 2013; Pagès-Escolà et al., 2019a) (Table 1). They are one of the most common invertebrates on benthic substrata, with 6063 marine and 108 freshwater extant species, most of them found in rivers and rarely in lakes (Bock, 1982; Ryland, 2005; Ballesteros, 2006; Wood et al., 2012; Pagès-Escolà et al., 2019a). They are also well-preserved in the fossil record due to their calcified skeleton, with 17,867 bryozoan species in the fossil record (Taylor and Waeschenbach, 2015; Pagès-Escolà et al., 2019a). An estimated 1350 extant and 2430 fossil species remain to be described by the final of this century (Pagès-Escolà et al., 2019a).

There are three classes of Bryozoa (Table 1). The Gymnolaemata are mostly marine species. It is the most species rich bryozoan group, and includes the order Cheilostomatida that has the most genera, over 600 (Table 1). They are characterized by body walls which range from entirely organic to rigidly calcified (Ryland, 2005). They originated in the Upper Ordovician (450 Myr ago). During the Late Jurassic (about 164–145 Myr ago) the order Cheilostomatida had evolved to have most of the complex skeletal structures seen today (Canu and Bassler, 1927; Taylor, 1990).

The Stenolaemata have only marine species, and most are fossil, except for those in the Order Cyclostomatida (Ryland, 2005). They are characterized by calcified body walls. The earliest fossil records were from the Lower Ordovician (500–430 Myr ago) (Ernst and Schafer, 2006). The Phylactolaemata are exclusively freshwater species, with membranous and gelatinous skeletons. They originated during the Upper Ordovician (Ryland, 2005).

Morphology

Bryozoan colonies vary in size and form from small colonies that create crusts a few centimeters across, such as the Mediterranean *Chorizopora brognartii*, *Puellina hincksi* and *Disporella hispida*, to large and rigid colonies of *Pentapora* species that can reach 1 m in diameter (Zabala, 1986; Cocito, 2004; Pagès-Escolà, 2019) (Fig. 1). In most species, the skeleton is external and calcified (Ryland, 2005).

Bryozoans do not have respiratory, circulatory or excretory systems (Bock, 1982; Zabala, 1986; Ryland, 2005). They have a nervous system that enables retraction and extension of their tentacles (see below) (Zabala, 1986; Ryland, 2005).

Table 1 Number of class, orders, families, genus and species for extant marine and freshwater bryozoans.

Class	Order	Habitat	Family	Genus	Species
<i>Gymnolaemata</i>	All	Marine	162	654	5206

Doctoral dissertation University of Barcelona.

Zooids

The functional units of bryozoan colonies are called zooids, which generally are enclosed in a case, the zooecium, that in many species secretes a rigid skeleton of calcium carbonate. The zooids are separated from each other by body walls with a system of pores which connect the zooids (Bock, 1982; Ryland, 2005). Zooids differentiate functionally and structurally. The most abundant zooids are feeding “autozooids” characterized by a ring of tentacles (lophophore) at their distal extreme, with cilia that create a flow of food particles to the mouth. Other zooids, called avicularias, are thought to be involved in the defense of the colony (Zabala, 1986; McKinney and Jackson, 1991; Ryland, 2005).

During the growth of the colony, some zooids sexually differentiate to have reproductive organs producing eggs or spermatozooids. The majority of bryozoan species have hermaphroditic zooids with simultaneous ovaries and testes. In some species, mature sexual zooids specialize as reproductive “gonozooids,” which are enlarged zooids with a chamber (oecium) and a body wall (ovicell) where internal fertilization occurs (Zabala, 1986; Ryland, 2005; Pagès-Escolà, 2019).

Fertilization can be external (in the sea), or internal in the gonozooids (Bock, 1982; Zabala, 1986). In addition, asexual reproduction processes can occur by fragmentation of the colonies (Zabala, 1986; McKinney and Jackson, 1991; Ryland, 2005).

The bryozoan life cycle is characterized by two phases. The first is characterized by sexual reproduction which produces a pelagic larva, and then a second phase of asexual growth or budding, which starts with settlement of the larvae (Ryland, 2005) and growth by budding of the colony. Fragmentation processes can also create new colonies and recruits (Linacre and Keough, 2003; O’Dea, 2006).

Ecology

Habitat

Most marine bryozoan species inhabit shallow waters, and some range as deep as 8000 m in the Indian and Pacific Ocean (Hayward, 1981). Bryozoans feed on planktonic particles captured by ciliated lophophore tentacles, which they can beat to create a current to the mouth (Ryland, 2005). Thus they are found in locations where the water current is sufficient to deliver food particles (Zabala, 1986).

Small species can create crusts on species, such as on the seagrass *Posidonia oceanica*, corals and seaweeds (Casola et al., 1987; Zabala et al., 1993; Manriquez and Cancino, 1996). Large bryozoans can be found attached to rocky seabed and walls, occupying exposed or epibiotic positions, such as the case of *Pentapora fascialis*, and inside caves, such as *Myriapora truncata*. Bryozoans such as *Pentapora fascialis* and *Turbicellepora avicularis*, have been found growing on plastic mesh and lost fishing lines lying on the seabed (Pagès-Escolà et al., 2019b) (Fig. 1).

Damage to bryozoan skeletons has been used as an indicator of impacts due to severe storms (Cocito et al., 2001) and scuba divers (Sala et al., 1996; Garrabou et al., 1998; Teixidó et al., 2013; De la Nuez-Hernández et al., 2014).

Biogeography

Bryozoans are widely distributed across the globe (Fig. 2), with a notably high diversity in the Southern Ocean (Barnes and Griffiths, 2008; Tittensor et al., 2010). This suggests that their latitudinal gradient in species richness may differ from the commonly accepted pattern that posits most diversity in the tropics (Chaudhary et al., 2016, 2017; Saeedi et al., 2017). However, despite their wide distribution, there has been no analysis of bryozoan biogeography at a global scale.

Due to the high abundance and diversity of bryozoans in the fossil record, they have been used to study paleoclimatic conditions (Berning, 2007), and are thus of scientific importance in understanding the Earth’s history.

Fig. 2 Recorded global distribution of bryozoans (GBIF, 2017; OBIS, 2017). Data from OBIS and GBIF Databases.

Social Importance

Economic

Although most bryozoan species have no known economic value, some species produce bioactive compounds or metabolites which have pharmacological applications. For example, bryostatins in *Bugula neritica* have potential anti-carcinogenic benefits (Jha and Zhi-Rong, 2004).

Ecological

Large bryozoan skeletons form habitats for other species that enhance associated diversity (Cocito, 2004; Lombardi et al., 2014). Most of these bryozoan skeletons are found in temperate regions, where the environmental conditions benefit the formation and persistence of these structures, even after they die (Wood et al., 2012). Their ecological benefits include providing additional available surfaces and crevices that protect other species from predation, and shelter from physical disturbances such as waves and light irradiance (Buss and Jackson, 1979; Bradstock and Gordon, 1983; Cocito, 2004; Wood et al., 2012; Lombardi et al., 2014). The presence of a bryozoan can also facilitate colonization by other bryozoan species (Cocito, 2004; Lombardi et al., 2014).

Invasive Species

There are around 86 bryozoan species recorded as invasive in the World Register of Introduced Marine Species (Ahyong et al., 2019). Most invasive species have been introduced through accidental transport as fouling on commercial ships or recreational boating (Kipp et al., 2010; Murray et al., 2011; Brine et al., 2013), with some examples of cosmopolitan invaders such as *Watersipora subtorquata* and *Bugula neritina* (Floerl and Inglis, 2005). The effects of introduced bryozoans include changes to the abundance and structure of kelp forests due to the effects of encrustation of some bryozoan species such as *Membranipora membranacea* (Scheibling and Gagnon, 2009; Krumhansl et al., 2011).

Climate Change

Previous studies showed that some species, such as the Mediterranean species *Pentapora fascialis* is sensitive to ocean warming and recurrent heat waves (Pagès-Escalà et al., 2018), making it susceptible to the effects of climate change. However, this has been only studied in the Mediterranean Sea and remains to be studied on other species and regions. Moreover, because bryozoan skeletons are calcified by calcite or aragonite they sequester carbon (Cocito et al., 2001; Wood, 2014) and may be vulnerable to ocean acidification (Smith, 2014).

Conservation

Because they provide biogenic habitat, conserving bryozoans benefits a wider variety of associated species. For this reason, it may be desirable to actively restore damaged populations (Pagès-Escalà et al., 2019b). Yet, despite their wide distribution, abundance and diversity, there is a lack of knowledge of many aspects of bryozoan biology and ecology, such as population dynamics, life cycles, and biochemistry.

Abstract

Similar to terrestrial biomes the marine domain has large areas with similar plant life forms. One of these is the seagrass biome. Seagrasses are flowering plants adapted to live in submerged coastal areas of tropical and temperate regions. Analogous to terrestrial biomes, seagrass provides feeding, breeding, and nesting habitats to associated fauna. It plays an important role in coastal environmental and ecological stability. However, the disturbance from human activities and natural disasters can accelerate seagrass loss. With the current awareness of the importance of seagrass biome, many conservation measures have been taken to protect it.

Introduction

The seagrass biome consists of meadows of plants similar to terrestrial grasslands distributed in tropical, subtropical, and temperate coastal areas (Green and Short, 2003). These angiosperm monocots have a well-developed root system to anchor to the seabed. Not only roots but rhizomes anchor seagrasses to the seabed and form underground biomass (Short et al., 2007). They have well-built mechanisms to survive in saline conditions in estuaries, lagoons and open seawater on the continental shelf and nowhere else. Seagrasses live their life in a submerged environment and have specialized pollen for underwater pollination (Green and Short, 2003; den Hartog and Kuo, 2006; Short et al., 2007).

Taxonomy

Phylogenetically, the seagrass biome is a functional group of four not necessarily closely related aquatic monocot families, namely the Zosteraceae, Cymodoceaceae, Posidoniaceae, and Hydrocharitaceae. They have 11 genera and 60–70 species (Green and Short, 2003; den Hartog and Kuo, 2006; Horton et al., 2018) (Table 1). The Zosteraceae has two genera; *Phyllospadix* and *Zostera*. The Cymodoceaceae has five genera *Amphibolis*, *Cymodocea*, *Halodule*, *Syringodium*, and *Thalassodendron*, family Hydrocharitaceae has three genera; *Enhalus*, *Halophila*, and *Thalassia* and family Posidoniaceae has one genus, genus *Posidonia*. All species in the families Zosteraceae, Cymodoceaceae, and Posidoniaceae are seagrasses. The family Hydrocharitaceae has only 3 out of 17 genera that are exclusively marine (den Hartog and Kuo, 2006).

A few monocot species in the families Ruppiaceae and Zannichelliaceae, which are primarily freshwater taxa, can live in brackish and marine conditions. They may occur in seagrass meadows among true seagrasses. Thus the seagrass biome is not comprised exclusively of certain plant families. *Ruppia tuberosa* from the family Ruppiaceae and *Lepilaena marina* from the family Zannichelliaceae are exclusively marine whereas *Ruppia maritima* forms meadows in both marine and freshwaters (den Hartog and Kuo, 2006). Molecular studies may reveal how seagrass evolved from marine algae to terrestrial plants and transitioned back to sea and clarify uncertainties of taxonomic relationships of seagrass species (Les et al., 1997). The genome of *Zostera marina* has been fully sequenced to identify the genomic losses and gains involved in adapting in the marine environment (Olson et al., 2016).

Environment

Physical variables such as depth, wave height, water clarity (a measure of light attenuation), temperature, salinity and photosynthetically active radiation and chemical parameters such as pH, and nutrients such as phosphate, nitrate and dissolved oxygen concentration, control the distribution of seagrasses (Short et al., 2001; Jayatilake and Costello, 2018). Depth is a proxy for light penetration through the water column and controls the vertical distribution of seagrass (Dennison, 1987; Duarte, 1991; Short et al., 2001; Duarte et al., 2007). The lower depth limit of seagrass distribution is known as the compensation depth (Gallegos and

From Jayatilake, D. R. M. and Costello, M. J. (2018). A modelled global distribution of the seagrass biome. *Biological Conservation* **226**, 120–126. <https://doi.org/10.1016/j.biocon.2018.07.009>.

Kenworthy, 1996; Hemminga and Duarte, 2000). At this level of depth, the amount of light reaching the seagrass plant is sufficient for photosynthesis and is equal to the plant respiration. The distribution of seagrasses may vary from 1 to 90 m (Duarte, 1991). The amount of light required for photosynthesis differs from seagrass species to species. The minimum light requirement for seagrass photosynthesis is identified as 10%–20% of sea surface light (Duarte, 1991).

Different seagrass species prefer a different level of salinity from brackish water to hypersaline seawater (Hemminga and Duarte, 2000; Hogarth, 2007). However, temperature is the primary environmental factor responsible for the global biogeography of seagrasses (Short et al., 2001; Jayatilake and Costello, 2018; Larkum et al., 2018). Temperature controls plant physiological activities such as photosynthesis, respiration, the seasonal cycle of growth, flowering and seed germination (Lee and Dunton, 1999; Short et al., 2001; Kaldy et al., 2015; Shimba and Jonah, 2017). Many studies have been focused on only one or a few species and how a few abiotic factors contributing to the distribution of seagrasses. A full study on how comprehensive all seagrass species response to all possible abiotic variables is yet to be done.

Biogeography

The composition of seagrass species varies from region to region. In 2003, Green and Short mapped the global distribution of seagrass species and identified 24 different regions each with different combinations of seagrass species (Green and Short, 2003). Short et al. (2007) identified six seagrass bioregions, namely: (1) Temperate North Atlantic (North Carolina, United States to Portugal); (2) Tropical Atlantic (including the Caribbean Sea, Gulf of Mexico, Bermuda, the Bahamas, and both tropical coasts of

the Atlantic); (3) Mediterranean (including the Mediterranean Sea, the Black, Caspian and Aral Seas and northwest Africa); (4) Temperate North Pacific (Korea to Baja, Mexico); (5) Tropical Indo-Pacific (East Africa, South Asia and tropical Australia to the eastern Pacific); and (6) Temperate Southern Oceans (New Zealand and temperate Australia, South America, and South Africa). The Tropical Indo-Pacific region had the highest species diversity with 24 species of seagrass (Short et al., 2007).

Seagrass distribution has been mapped with remote sensing and satellite imagery, aerial survey and photography, multispectral scanning, underwater video, permanent transects, occurrence records from herbariums, online database depositories, and modern computerized modeling methods (Kirkman, 1990; Green and Short, 2003; Jayathilake and Costello, 2018). Recently, the world maps of seagrass have been updated by combining over 43,000 field data records with 13 environmental variables in species distribution models (Fig. 1). The map has 30 arc sec resolution (c. 1 km at the equator) (Jayathilake and Costello, 2018) and is available at <http://data.unep-wcmc.org/datasets/46>. However, this map predicts the potential distribution of seagrass and not its abundance. Whether seagrass occurs and how much occurs at any location requires local-scale observations. Such studies can find seagrass has been lost due to human impacts (see below).

Role in Ecosystems

The seagrass biome has a three-dimensional structure analogous to terrestrial biomes. It has a vertical and horizontal distribution which provides shelter, feeding, breeding, nesting habitats for diversity animals (Beck et al., 2001; Orth et al., 2006; Jayathilake and Costello, 2018). This biome has high primary and secondary productivity and provides a home to many threatened species including dugong (*Dugong dugon*), fan mussel (*Pinna nobilis*), dwarf seahorse (*Hippocampus zosterae*), and green sea turtle (*Chelonia mydas*) (Preen and Marsh, 1995; Orth et al., 2006; Short et al., 2007; Hughes et al., 2009). As a nursery habitat for juvenile fish, it provides a significant contribution to fisheries (Lilley and Unsworth, 2014). Seagrasses are considered ecosystem engineers as they can control and maintain suitable habitat for other species by improving water quality, light availability, sediment stability, and increasing carbon and other nutrient availability (Hemminga and Duarte, 2000; Duarte, 2002; Orth et al., 2006; Bos et al., 2007; McGlathery et al., 2012).

Seagrass meadows are an important feeding ground for many marine herbivores and these secondary producers support higher trophic levels in the foodwebs (Hemminga and Duarte, 2000; Duarte, 2002; Cullen-Unsworth and Unsworth, 2013). Seagrasses capture and store carbon dioxide in their above ground and underground body mass known as blue carbon (Nellemann et al., 2009; Macreadie et al., 2014). Indeed a recent mapping of the seagrass biome (Fig. 1) has doubled previous estimates of the area it covers (Jayathilake and Costello, 2018). This means its global contribution to carbon sequestration may be higher than the current prediction. In addition to the above ecological benefits, the seagrass biome has nonconsumptive value in tourism, research, education, religion, and culture (Cullen-Unsworth and Unsworth, 2013).

Fig. 1 The MaxEnt model predicted environmental range for the seagrass biome. From Jayathilake, D. R. M. and Costello, M. J. (2018). A modelled global distribution of the seagrass biome. *Biological Conservation* **226**, 120–126. <https://doi.org/10.1016/j.biocon.2018.07.009>.

Conservation

Seagrass cover has been declining globally at a rate of 0.9% per year before 1940 and 7% per year after 1990 (Waycott et al., 2009). For the last 125 years, more than 51,000 km² area of seagrass meadows has been lost due to natural and anthropogenic disturbances (Orth et al., 2006; Waycott et al., 2009). These are also vulnerable to natural disasters at both regional (storms, cyclones, floods, hurricanes, earthquakes, disease, grazing by herbivores) and global (warming) scales (Short and Wyllie-Echeverria, 1996; Short and Neckles, 1999; Marbà and Duarte, 2010). Human-induced disturbance such as dredging, sedimentation, eutrophication, habitat fragmentation, boat anchoring and propeller scars accelerate seagrass loss (Short and Wyllie-Echeverria, 1996; Montefalcone et al., 2010). Because of their ecological importance as one of the most productive coastal vegetation, it is essential to understand in the local and global distribution, uses, threats, management and conservation values. Thus, in some areas active seagrass restoration has been undertaken. For example, fishermen in Japan created a Marine Protected Area where they banned dredging and replanted seagrass to help restore fisheries (Tsurita et al., 2017). Similar active seagrass restoration has been used to help coastal ecosystems recover from eutrophication, pollution, and dredging (van Katwijk et al., 2016).

Abstract

The kelp biome is an assemblage of forest forming seaweeds of the order Laminariales (macroalgae). They occur in cool waters in shallow temperate and deep tropical seas. Similar to terrestrial forests, the kelp biome has a three-dimensional structure which provides habitats for a diversity of associated fauna and flora. Sea surface temperature, water motion, light penetration and nutrient availability control the distribution of kelp forests. Factors such as violent storms, diseases, environmental fluctuations, overgrazing, pollution, and sediment influx from land can cause loss of kelp forests. Establishing marine reserves and improving water clarity by reducing sediment inputs can restore and protect kelp forests.

Introduction

The kelp biome consists of species from the order Laminariales (brown algae) (Smale and Moore, 2017). They attached to rocky sea beds in the lower intertidal and shallow subtidal zones in temperate and subpolar region (Teagle et al., 2017). Similar to terrestrial biomes and other marine biomes (seagrass, mangrove, and zooxanthellate corals), the kelp biome has a three-dimensional (3-d) structure with plants attached to the rocky seafloor with a holdfast (Smith, 2000). These giant underwater primary producers exhibit a high diversity in growth forms and many of them grow above 30 m in length (Wernberg et al., 2019).

Morphology

As kelp members are brown algae, the plant is known as a thallus and in plural thalli. The thallus has a holdfast, stipe and blades or frond (Dayton, 1985; Wernberg et al., 2019). Similar to the angiosperm roots, the holdfast attaches the thallus to the rocky substratum. The stipe is analogous to the stem of plants and fronds function as leaves. The arrangement of stipe and fronds are the primary morphological characters to identify different species of kelp (Wernberg et al., 2019). These algae have the ability to change their morphology according to environmental conditions such as high wave action and turbulence, and population density (Fowler-Walker et al., 2006; Arenas and Fernandez, 2000).
